LIST OF CONTRIBUTORS TO VOL. XLVI.

Abbott, Dr. George E., New York.
Abrahams, Dr. R., New York.
Abrams, Dr. Albert, San Francisco, Cal.
Adams, Dr. Robert S., New York.
Aiken, Dr. Hugh K., Laurens, S. C.
Aiken, Dr. Wm. F., Savannah, Ga.
Alger, Dr. Ellice M., New York.
Ambrose, Dr. Daniel R., New York.
Ashmead, Dr. Albert S., New York.
Aulde, Dr. John, Philadelphia, Pa.

Baginsky, Dr. Rudolf, Berlin, Ger.
Bannan, Dr. Theresa, Syracuse, N. Y.
Barry, Dr. John H., Long Island City, N. Y.
Baruch, Dr. Simon, New York.
Bashore, Dr. Harvey, West Fairview, Pa.
Beck, Dr. Carl, New York.
Beebe, Dr. Alfred L., New York.
Bellamy, Dr. Russell, New York.
Benedict, Dr. A. L., Buffalo, N. Y.
Biggs, Dr. Hermann L., New York.
Blair, Dr. Louis E., Albany, N. Y.
Bleyer, Dr. J. Mount, New York.
Blumenthal, Dr. Oliver A., Syracuse, N. Y.
Bogle, Dr. J. C., Danville, Ky.
Bosworth, Dr. F. H., New York.
Bottome, Dr. Frank A., New York.
Brandenburg, Dr. F. D., Cleveland, Ohio.
Brewster, Dr. J. D., Windsor, Vt.
Briggs, Dr. M. D., Champlain, N. Y.
Brown, Dr. Sanger, Chicago, Ill.
Bull, Dr. William T., New York.
Bullitt, Dr. James B., Globe, A. T.

Cadwallader, Dr. Rawlins, Fall River Mills, Cal.
Callender, Dr. C. H., New Boston, Mass.
Carleton, Dr. Th. B., Sabathu, India.
Carroll, Dr. C. H., Pavaris, Fla.
Cartwright, Dr. Silas S., Roxbury, N. Y.
Caverly, Dr. C. S., Rutland, Vt.
Chapin, Dr. H. Dwight, New York.
Chapman, Dr. W. L., Lynn, Mass.
Clark, Dr. L. Pierce, Middletown, Conn.
Cleaves, Dr. Margaret A., New York.
Coleman, Dr. Warren, New York.
Collins, Dr. Joseph, New York.
Collyer, Dr. H. L., New York.
Comegys, Dr. C. G., Cincinnati, O.
Conklin, Dr. W. J., Dayton, Ohio.
Conn, Dr. H. W., Middletown, Conn.
Cordier, Dr. A. H., Kansas City, Mo.
Craig, Dr. Thomas C., U. S. Navy.
Crary, Dr. George W., New York.
Crosse, Dr. W. A., Jenkinton, Pa.
Crossfield, Dr. Fred. S., Hartford, Conn.
Cushing, Dr. Clinton, San Francisco, Cal.

Dalrymple, Dr. F. W., New Rochelle, N. Y.
Daly, Dr. W. H., Pittsburg, Pa.
Dana, Dr. Charles L., New York.
Dawbarn, Dr. R. H. M., New York.
Dickinson, Dr. George S., Erie, Pa.
Dickinson, Dr. R. L., Brooklyn, N. Y.
Dixon-Jones, Dr. Mary A., Brooklyn, N. Y.
D'Oench, Dr. F. E., New York.
Dowd, Dr. Charles N., New York.
Dwight, Dr. Thos., Nahant, Mass.

Eastman, Dr. Jos., Indianapolis, Ind.
Edes, Dr. Robert T., Boston, Mass.
Ely, Dr. John Slade, New York.
Embden, Dr. Oscar, Brooklyn, N. Y.
Engman, Dr. Martin F., New York.
Estes, Dr. W. L., South Bethlehem, Pa.
Ewing, Dr. A. C., Salt Lake City, Utah.

Fischer, Dr. Louis, New York.
Flagg, Dr. R. N., Yonkers, N. Y.
Foster, Dr. Burnside.
Francis, Dr. Richard P., Montclair, N. J.
Frank, Dr. J., Chicago, Ill.
Freeman, Dr. Leonard, Cincinnati, Ohio.
Freeman, Dr. Rowland Godfrey, New York.
Friedenwald, Dr. Julius, Baltimore, Md.

Gage, Dr. W. V., McCook, Neb.
Gardner, Dr. H. D., Scranton, Pa.
Garrigues, Dr. Henry J., New York.
Getz, Dr. Charles, Baltimore, Md.
Gibson, Dr. C. L., New York.
Gifford, Dr. H., Omaha, Neb.
Gleason, Dr. W. S., Newburg, N. Y.
Godfrey, Dr. Guy C. M., U S.A.
Goffe, Dr. J. Riddle, New York.
Goldstein, Dr. Samuel, New York.
Gorton, Dr. Eliot, Morris Plains, N. J.
Gowers, Dr. W. R., London, England.
Grandin, Dr. Egbert H., New York.
Grissim, Dr. J. D., Paterson, N. J.
Groom, Dr. W. S., Britt, Ia.
Gross, Dr. M., New York.
Guthrie, Dr. W. E., Bloomington, Ill.

Hance, Dr. Irwin C., Saranac Lake, N. Y.
Hartley, Dr. Frank, New York.
Hartwig, Dr. Marcell, Buffalo, N. Y.
Hawkes, Dr. J. Marshall, New York.
Healey, Dr. Joseph S., New York.
Heffron, Dr. J. L., Syracuse, N. Y.
Herrick, Dr. H. J., Cleveland, O.
Herrick, Dr. J. F., Ottumwa, Ia.
Higgins, Dr. F. W., Syracuse, N. Y.
Hill, Dr. J. Sutcliffe, Bellows Falls, Vt.
Hill, Dr. W. J., Statesville, N. C.
Hinde, Dr. Alfred, Chicago, Ill.
Hochlerner, Dr. R.
Hoelscher, Dr. J. H., Chicago, Ill.
Hopkins, Dr. George G., Brooklyn, N. Y.
Horton, Dr. D. B., Batavia, N. Y.
Horton, Mr. Thomas, Montclair, N. J.

ENTERIC FEVER IN INFANCY.

BY WILLIAM B. NOYES, M.D.,

NEW YORK.

THE recent epidemic of typhoid fever in Montclair, N. J., arising from a polluted milk supply, developed an unusually large proportion of cases in young children. We are so apt to consider typhoid a disease of older children and adults, that cases occurring in earlier infancy have a fair chance of not being diagnosed unless occurring in connection with other cases. Northrup, in his long experience in the Foundling Asylum, among ten thousand cases has never had a case of typhoid, and he has never seen a case under two years in his entire experience. Huber has seen but three or four cases, Holt has seen no cases under sixteen months, Prudden has seen nothing of it in a pathological way, and others of large experience have seen little of typhoid during the first two years.

The first case I wish to report is one which I followed very closely during its entire course, and can vouch for its absolute accuracy.

CASE I.—A. G. N——, eleven months of age, a healthy male child of somewhat nervous temperament, of healthy parents, with no tendency to tuberculosis or any other disease. Had suffered from scarcely any of the ordinary diseases of childhood. He was taken to Montclair for a visit of ten days soon after weaning, and was fed on milk diluted with barley-water, not boiled or sterilized. He rapidly improved in health during these days. Soon after his return to the city he became fretful, restless, and had a slight fever attributed to his "cutting teeth." When I saw him first, except for a slight angina and a temperature of 102° F. in the evening, there was nothing characteristic or positive in his condition except the probability that he was developing something. For two days he improved, though still with a moderate temperature. On the next day he had a roseola, which disappeared in a few hours.

March 27th.—His temperature was 102.6° A.M.; 103 8° F., P.M.; and for the first time he appeared very sick. Moderate diarrhœa with colicky pains, straining at stool. Tongue coated. Vomiting occasionally.

Diagnosis, gastro-enteritis. Treatment, a mixture of hydrochloric acid, pepsin, and bismuth.

March 28th.—Temperature, 102.6° to 104° F. Moderate diarrhœa with colic.

March 29th.—Temperature, 102.6° to 103.4° F. Diarrhœa with frequent stools of a very foul odor. Tongue coated white; tip and sides red. Lungs gave physical signs of bronchitis. No angina. Slight dulness under the left scapular. Breathing rather high-pitched and rapid. Very fretful. Hands brought frequently to the head as if suffering pain. Pupils equal. No other definite symptoms.

March 30th.—Temperature, 101.8° A.M. to 102.8° F. P.M. Condition somewhat better. Lung symptoms less marked.

April 1st.—Temperature, 102.2° A.M., 103° F. P.M. Patient being in better condition, it was decided to move him back to the country for a change of air, and to escape suspected plumbing. No bad results from the trip. Dr. H. B Whitehorn, of Verona, N. J., after this time associated with me in the case. During the two weeks which had elapsed since he had left Montclair, about fifty cases of typhoid fever had developed, and about this time it was publicly recognized that the origin of every one of these cases was due to one cause alone, the polluted milk served to the families of all the cases by one dairyman, G——, who had two cases of typhoid in his family one month before, and had infected his well, and used the well-water to wash the cans and bottles. The baby had fed for ten days on this milk. The combination, therefore, which now appeared before us, of a high continued temperature during the past week, the coated tongue, with clean margin, some tympanites, all this pointed directly to a diagnosis of typhoid. The stools, which, on a napkin, appeared similar to an ordinary stool in diarrhœa trouble, examined in a vessel were not unlike the typical pea soup discharges.

April 2d.—Temperature, 104° F.; pulse, 160; respiration, 25; stools, 4. Rose spots first seen on abdomen and chest, very marked, disappearing on pressure; very distinct when bathed. Patient coughed occasionally and vomited once or twice. Another case of typhoid in the family, the nurse of the baby, who had used the same infected milk, diagnosed at this time.

April 3d.—Temperature lower, 103° F.; pulse, 160; respiration, 25. The diet, which had consisted of sterilized milk and barley-water, was not agreeing well, vomiting and diarrhœa being troublesome. Changed to a combination of Pasteurized milk, lime-water, and cream, which was afterward well borne.

April 4th.—Temperature, 101.5° to 102.5° F.; pulse, 150; respiration, 35. Occasional coughing; baby very restless, giving signs of pains in the head.

April 5th to 7th.—Patient doing well, restless at times. Temperature reached 100° to 101° F.

April 8th.—Baby still fretful and cried occasionally with a sharp shrill cry. Some undigested milk in the defecation.

April 9th.—Baby slept fairly well, nervous when awake, same shrill cry as before. Temperature arose from 100.2° to 104° F. Pulse, 150; respiration, 27. It was noticed that he held his head drawn back and made continual motion with his hand as if to grasp some object. Pulse feeble, extremities cold and somewhat cyanotic. Under vigorous stimulation the condition passed away.

April 10th.—Temperature, 102.6° to 103° F. Pulse over 160. Patient somewhat better, treated for tendency to convulsions by sedatives, and systematic heart stimulation by means of champagne and minute doses of heart tonics.

April 11th.—Temperature, 101° to 104° F. Pulse, 160 to 180; respiration, 30. A condition of irregular pulse and cyanosis was noticed which reacted to heart stimulation. Condition of rigidity of the neck, opisthotonos, general hyperæsthesia, inco ordination of eyeballs, peculiar cry, with occasional convulsive movements of the hands, became now very marked. Dr. Huber, of New York, called in consultation.

April 12th.—Condition of patient very poor. Temperature, 102.4° to 104.8° F. An irregular feeble pulse and great restlessness calling for careful heart stimulation. Urine carefully examined, no trace of albumin found. A third case of typhoid fever in the family developed at this time.

April 13th.—Temperature, 102.2° to 103.4° F. Respiration, 30 to 40 Rapid and shallow. Pulse 152, slightly irregular. One very bad spell in the afternoon,

the most serious attack of collapse thus far, with cyanosis and faint pulse, checked by vigorous stimulation and high hot enema.

April 14th —Temperature, 101.5° to 102.8° F.; pulse, 152 to 110; respiration, 55 to 53; difficulty in getting him to swallow anything except champagne, which he took readily. At times the convulsive movements and symptoms of heart failure.

April 15th.—*Statu quo.* Temperature, 101° to 103° F.

April 16th.—Quiet day until a severe collapse in the afternoon, which was nearly fatal. All forms of stimulation were used from 2 to 6 P.M., including artificial respiration, oxygen, electricity, and other agents, without response. Vomiting of a greenish-brown fluid. A combination of tincture of musk, aromatic spirits of ammonia, spirits of camphor, and a one per cent. solution of nitro-glycerine, one minim of each every five minutes in the mouth by a medicine dropper, was followed by improvement and restoration to a fairly good condition.

April 17th —Temperature, 104° F.; pulse, 152. Convulsions and collapse at 5 A.M ; died from heart failure and respiratory paralysis, 10 A.M.

Of 115 cases of typhoid and similar cases occurring in Montclair and vicinity, where the infected milk was sold, 7 were reported of three years of age or younger, all having been fed on this milk.

Case II.—Reported by Dr. Smith. Girl, aged three, previously healthy, had subsisted entirely on the milk from the G—— dairy. When first seen, March 12th, had diarrhœa, tympanites, eruption, and all the symptoms of typhoid. The case ran an uneventful course and terminated after two weeks.

Case III.—Reported by Dr. Brown. B B——, aged eighteen months. Female, one of three children, aged one and a half, three, and five years, respectively, who were all attacked with typhoid; sick about twenty-eight days, with bronchial catarrh, high temperature, very fretful, constipated; no rash, mouth, or nervous symptoms; diagnosis, typhoid, on account of the epidemic.

Case IV.—Reported by Dr. Newton. H. B——, aged eleven months. Male. Treated from April 1st to April 11th; entire illness, sixteen days. Eruption present, eight to ten petechiæ noted. Temperature about 102° F. Some tympanites. Moderate diarrhœa. Yielded readily to a diet of boiled milk and pepsin. Dr. Newton was first called in to see the patient on account of sore mouth, and found an aphthous condition of the mouth, gums sore and bleeding. Tongue had a heavy brownish-white coat. Breath offensive. Colicky pains until relieved by calomel. Patient had an uneventful run of fever and short convalescence; never vomited, and never refused his bottle.

Case V.—Reported by Dr. Wilson, of Bloomfield. Infant, aged thirty months. First seen about April 25th. Sick two weeks. Eruption present. A mild case.

Case VI.—A boy, under three years, reported by Dr. Shelton, of Montclair, suffered from typhoid at the same time that a brother, aged five years, and a sister, aged six years, all having been fed on the infected milk. Fever lasted four weeks, varying from 100.5° F. A.M , to 103° to 104° F. P.M. Temperature curve fairly typical. Eruption present. Extreme restlessness and tendency to scream out suddenly noted. The pulse generally 128, at times intermittent. Distended abdomen, considerable flatulence at times. Frequent offensive stools, somewhat formed, with greenish particles. Urine negative. Occasional coughing. Otherwise uneventful course and recovery. The case of the girl, aged six years, was exceedingly severe, with obstinate constipation for many days, great prostration, emaciation, and bed-sores. Temperature reaching 104.5° F. the second week. Great restlessness, coughing, delirium, abdominal pain, and offensive breath.

Case VII.—Communicated by Dr. Brown, of Montclair. Child, aged three years, very sick for twenty-eight days. Sister of Case III. Temperature running from 103° to 105° F. for some time. Marked nervous symptoms for several days. Great restlessness, tossing its head from side to side. Rigidity of muscles of the neck. Opisthotonos. Almost complete blindness for five days, strabismus at times, hydrocephalic cry. Tympanitic abdomen, no eruption, no urinary symptoms, tongue coated and moist. Picked at its nose until the nose became raw. Case recovered under treatment of bromides and phosphoric acid. Constipation was marked. Dr. Brown has seen six cases of clear typhoid, under five years, in this epidemic, three under three years of age. He recalls in previous years a number of cases with a high fever running for several weeks, with constipation more frequently than diarrhœa, no noticeable rash, which he now considers, in the light of his experience gathered in Montclair in the recent epidemic, to have been undoubtedly enteric fever.

Case VIII.—Reported by Dr. Newton. E. B——, girl, aged two and a half years. Sister to Case IV. Actively sick about one week, with temperature reaching 103° F., lowest 98° F. Eruption; no diarrhœa. Treated from April 6th to May 5th. An exceedingly mild and uneventful case. An older sister of this case, aged seven years, also sick with typhoid fever, with a maximum temperature of 104° F. Excessive eruption for two weeks. At one time one hundred and fifty petechial spots on body and limbs.

We have given our own case in detail, not because it is the youngest case on record, for it is not, but the cases on record usually quoted are too abbreviated to be entirely trustworthy. There are cases quoted by various authors occurring soon after birth and during the first year. Pregnant mothers contract typhoid, and give birth to infants who develop symptoms of typhoid a few days later. Eichhorst mentions the following examples in early infancy: 1. Found twice by Charceley in the new-born. 2. Hastelius: In a fœtus taken dead in the eighth month from its mother, who had died from typhoid, there was found splenic tumor and marked infiltration of intestinal follicles and mesenteric glands. 3. Neuhaus has found typhoid bacilli in the organs of a fœtus. 4. Chantemesse and Vidal found it in the blood of the placenta, and proved that the typhoid bacilli could be transferred to the fœtus by experiment. 5. Eberth in the heart and in the fœtal membranes and placenta, expelled in the third week of an attack of typhoid. 6. Hildebrand demonstrated them in the spleen, liver, mesentery glands, and nervous system. 7. Reher made successful cultures from the fluids in the liver of a fœtus.

The youngest case recorded contracting the disease itself is at the age of four and a half months. Reported by Ogle in *The Lancet*, 1892. After a week of fretfulness, fever, and indefinite gastro intestinal symptoms, the case yielded, on autopsy, swollen and reticulated Peyer's patches with ragged ulcers, partly ulcerated solitary follicles, enlarged mesenteric glands, and enlarged and softened spleen.

Earl, of Chicago, reported a case, five months four days, with fever, diarrhœa running a mild course like an innocent gastro-enteritis. Finally, after suddenly developing symptoms of collapse and symptoms strongly resembling peritonitis, the infant died, and was found to have swollen solitary follicles, partly ulcerated Peyer's patches, and enlarged mesenteric glands. Peritoneum normal.

Murchison showed intestines of an infant of six months to the London Pathological Society, which had been attacked with typhoid at the same time as his mother, and had the typical lesions of typhoid in a marked degree.

Henoch reports two cases, at six and seven months, with diarrhœa, splenic tumor, bronchial catarrh, otitis, somnolence, characteristic fever curve. Autopsy showed very slight changes, slight swelling of single mesenteric glands, one Peyer's patch swollen. He pronounced the cases as undoubtedly typhoid.

Abercrombie described a case in an infant of six months and one at seven months, with autopsy yielding typhoid lesions. Shadler narrates a case of a seven

months' infant whose mother died about the same time from typhoid.

England[1] quotes in detail a case at eight months, with vomiting, diarrhœa, tympanites, enlargement of liver and spleen, rose spots, and fever for three weeks.

Fuller, *The Lancet*, 1892, a case at nine months characterized by diarrhœa, headache, continuous fever, not over 102° F. for ten days, tympanites, pain on deep pressure. Autopsy showed the typical lesions of typhoid. Long[2] reports in detail a case, of one year, with typical typhoid symptoms

Dr. Huber saw two cases some years ago; one, an infant of eighteen months, the other, two years and six months, both occurring at the same time with other cases in the same family. Indefinite symptoms, but diagnosis clear from the presence of other cases.

Northrup had a case of a child two years of age, in the Presbyterian Hospital, who caught typhoid from its mother who was sick at the same time. The eruption and ordinary symptoms of typhoid were present. The patient made a prompt recovery.

Jacobi has seen many cases of typhoid in infancy.

If these cases are authentic, and there is little doubt that they are, we cannot help thinking that we have before us a disease, rare not because it does not occur, but rare because it is not recognized when it does occur. Henoch states his firm belief that the greater part of cases formerly called gastric fever (febris gastrica remittens) are really typhoid. The "febriculæ" so frequently mentioned in text-books, and vague intestinal disorders so often seen in clinics, with little systematic study of their temperature, are very often probably abortive typhoid fever in their natures, terminating between the tenth and twentieth day with absorption of inflammatory products and no ulceration.

Vogel reports, out of 1,017 cases, 7 under one year; Montmellen, out of 295 cases, 15 under two years; Henoch, out of 280 cases, 8 under two years; Earl, out of about 40 cases, 7 under five years. The undeveloped condition of the glandular structure of the intestines, as urged by some writers, might vary the pathological changes and symptoms, but cannot render infants of any age proof against infection, if they drink any infected water or infected milk, or use infected bottles, or are in close contact with typhoid patients.

In the prodromal period symptoms are not pronounced. The onset will, in most cases, be so insidious that it must be a number of days before a correct diagnosis can be made with any degree of certainty. If there is diarrhœa, a gastro-enteritis or entero colitis will explain all the symptoms that have yet appeared. If there be actual constipation, or merely occasional movements consisting of somewhat altered or putrid stools, a diagnosis of ptomaïne poisoning from some undigested fermenting substance in the intestine will explain all the symptoms. This is not really a false diagnosis, it merely does not state what is the bacterial agent that causes the ptomaïne poisoning.

Donkin states that 24 out of 62 of his cases in children showed a more definite onset of the disease than in adult life. Headache, shivering, vomiting, pain in the belly, back, or legs. Henoch says that it is rare to begin with a chill. Brown, of Montclair, has noted in several cases a rather abrupt commencement.

The fever in the cases occurring in infancy is apt not to present a typical curve at first, for there are so many causes that influence the temperature of a child that would not affect an adult. The fever may be moderate throughout, or it may reach a high point early, and the original diagnosis be changed solely because the temperature is too high and too continuous to be caused by a simple enteritis.

Two distinct periods that may be found in the temperature of an ordinary typhoid in an adult: (1) disturbance due to the typhoid bacilli, causing a sub-continuous fever; (2) disturbance due to the formation and separation of intestinal sloughs, causing a remittent fever, are apt in early childhood to be varied because the second element is imperfect, short, or often entirely absent, due to the fact that the intestinal lesions frequently undergo resolution without any ulcerations (Keating).

Garlock[1] states that the process in Peyer's patches is generally limited to the lymphoid cells and is superficial. The proliferated cells undergo fatty degeneration and are absorbed without formation of ulcers. A fever after fourteen days is due to absorption through open ulcers. And few children with such ulcers can escape a secondary fever.

The milder degree of intestinal lesions, and especially the absence of ulcers, would make us expect that we should find less abdominal tenderness, less pain, less diarrhœa, and less tympanites than in the adult, which all recorded cases show to be undoubtedly true. Gerhart states that the swelling of Peyer's patches shows itself earlier than in adults, and is seen with greatest frequency near the ileo-cæcal valve, often reaching higher. This swelling is sufficient to cause the patches to protrude out beyond the mucous membrane in projections that are frequently the seat of excoriations and little ulcers. These may later develop deep ulcers and sloughs, as occurred in twenty-nine out of his forty-four examinations. On the other hand, this frequently clears up without ulceration. Henoch holds that the ulcers are comparatively rare and of small size. He found them in 13 out of 23 autopsies of his 239 cases in children. He says that when they occur they are generally small, shallow, and instead of occupying the whole of a Peyer's patch occupy merely a part. The Peyer's patches may form what he calls "plaques molles," a condition of fatty degeneration of the new-formed cells resulting finally in resolution, or they may form hard plaques, indicating an infiltration of the entire gland tissue and tissues beneath, which will ultimately result in the formation of ulcers.

Granted that typhoid fever is commoner than we have realized, what symptoms will enable us to recognize one of these cases or make an early diagnosis?

1. Any long-continued fever that will not yield to appropriate doses of quinine is suspicious, especially when higher in the evening, and when no existing conditions of the throat and lungs or bowels suggest an explanation. A temperature remaining continuously high, and yielding, if systematically taken, a fairly typical typhoid fever curve after a few days. Jacobi lays stress on the probability of typhoid with a continuous high fever, which is well borne by the infant.

2. Gastro-intestinal disorder, especially when a decided tendency to constipation is present; putrid stools of an especially offensive character and odor when there is any diarrhœa. If these are only seen on the diaper they will not look very different from the green spinach stools that occur in other diarrhœas, because the fluid is soaked up on the napkin. If seen in a vessel, the thin, semifluid character, greenish particles, and all the characteristics of a typical "pea soup" stool are present. If there is trouble with insufficient digestion of food, the lumps of undigested casein will somewhat change the appearance. The lack of acute symptoms of an intestinal nature is more characteristic than violent symptoms. Vomiting may or may not be present.

3. The first absolutely sure symptom is the appearance of rose spots, which may come early or late, or in two or three crops, and are said by some writers to occur quite as regularly as the rash in scarlet fever. Brown, of Montclair, among his six cases has seen several with slight rash or no rash at all. Earl found them in all his cases but three.

Roseola, or sudamina, or other indefinite rashes, may be present at any stage, and possibly confuse diagnosis.

4. Symptoms of headache, which a baby will indicate by rubbing or picking at its head, nose, or ears, or burrowing its head back in the pillows, but not by active head symptoms which would characterize meningitis. As

[1] Canada Medical Record, vol. xx., p. 25.
[2] Archives of Pediatrics, 1893, p. 53.

[1] Transactions of the New York Medical Association, 1891.

the disease goes on these head symptoms will frequently increase.

5. A tongue coated with yellowish or brownish-white fur, generally red at the tip or sides. It may be so heavily coated and the entire mouth so affected that a condition resembling aphthous stomatitis may be present. In the case reported by Dr. Newton this was the symptom that first caused the physician to be called in; but the condition of sordes is not as frequent in infants as in adults.

6. Enlarged spleen is very important when found, but not always to be accurately demonstrated in a young child, especially if tympanites is present.

7. Tympanites, sometimes excessive, but in most recorded cases very moderate.

8. Bronchitis seems to be almost as regular a symptom as in measles, agreeing with the pathological changes demonstrated by Uffelman of swelling and redness of bronchial tubes, but the breathing is, later, too superficial to make râles.

9. There may be angina. I have seen it twice, once in the present case, and once in an older typhoid patient. Henoch says that it is not uncommon. When found it is apt to confuse rather than help the diagnosis.

10. The stools, when carefully examined very early in the disease, may contain typhoid bacilli, but this has very rarely been detected in most of the recorded cases. If it could be, it would be of very great importance as an absolute means of diagnosis, but after the second week it is very rare to be able to find them.

When the diagnosis is made from the spots, spleen, tongue, and temperature, as the cases in children advance, several variations in typical symptoms of adults are to be expected. Ileo cæcal tenderness or gurgling is hard to satisfactorily determine, and when present is worthless because it can be found in various other diarrhœal diseases in children. The hard, dry tongue, the swollen tongue, or excessive sordes, are rarer in children. Hemorrhage or perforation is very rare. As a whole, the severer symptoms common to adults frequently fail.

The nervous symptoms are interesting and will often confuse the diagnosis from the beginning, suggesting acute, subacute, or tubercular meningitis, according to their severity, especially if the previous history of the child and family is suspicious. The regular occurrence of headache, even in the youngest, has been noted; and though more difficult to detect in the very young infants, will, in most cases, be suggested by the actions of the child.

Intestinal cases present quite a variety of reflexes in the head; for instance, a constant picking of the nose, which was noticed from the beginning to the end in my own and in other cases, instead of being a local irritation is a reflex, which Louis Starr called a regular symptom of gastric and intestinal irritation. It occurs also in tubercular meningitis Henoch says it is an early typhoid symptom, but may last throughout. Picking at ear may accompany otitis.

As stated by Keating, in infants and young children nocturnal delirium, which an adult would present in early weeks of typhoid, is accompanied, or more often replaced, by sudden sharp and prolonged outcries, with great restlessness or excitement not easy to pacify. This will resemble a hydrocephalic cry, and is again a very startling symptom. Extreme restlessness is almost sure to occur. Earl also calls attention to continued crying at night, stiffness of the neck, jerking of the muscles. There may be apathy or a condition of coma, when the muscles become lax and the movements of the eyes are no longer co ordinated. Blindness may occur as in Case VII.

In spite of all these symptoms real meningitis, as a complication, though it can occur, is exceedingly rare. Henoch has never seen a case. But the symptoms I am about to relate are very much like the symptoms of meningitis.

In my case, about the end of the second week, following a little trouble in digestion, vomiting occurred and general irritability increased. Temperature rose four degrees, and there developed a stiffness of the neck and back, which became after a time a condition of opisthotonos. There was inco-ordination of eyeballs and a peculiar movement of both eyes upward and to the side, great hypersensitiveness to sound, light, and touch, especially touching the head. Irregular and at times convulsive movements, especially marked in the left arm and leg, and continued twitching of the fingers. The baby cried out frequently in a new and strange way, and the pulse became very rapid, 160 to 180, irregular and occasionally intermittent. Respiration rapid, irregular, and sometimes sighing. All this pointed in my mind almost certainly to an acute meningitis. Dr. Huber, who saw the case at this time, while agreeing absolutely with the original diangosis of typhoid fever, held that the presence of an active meningitis might be ruled out for the following reasons: 1. The fontanelle was depressed, not elevated. 2. The child was bright enough to notice things. 3. No tache cerebral. 4. No boat-shaped abdomen. 5. The vomiting had not been expulsive. 6. The photophobia and hypersensitiveness to light and sound were less than one would expect in an acute meningitis. The entire condition, acute as it seemed, he held to be a passive congestion in the vessels of the brain caused by the weak heart, and held that heart stimulation already begun would remove these symptoms, which actually took place within a few hours.

I have mentioned this in detail because it shows how far an extreme case of the ordinary nervous symptoms of typhoid can simulate meningitis. Henoch reports a case of tremor and stiffness of the extremities, constant jerking of the same, which showed on autopsy no brain lesion. Also one where there was contracture of both legs and right arm, continued grinding of the teeth, yielding at autopsy only slight changes. Also another case of a girl, four years of age, who showed distinct stiffness of the neck, later actual opisthotonos, and marked contracture of the neck, with grinding of the teeth. Autopsy showed no brain lesion. Foster reports a case of trismus and opisthotonos which lived. Brown's case (quoted as Case VII.) had opisthotonos, blindness for several days, and numerous other severe brain symptoms, and recovered. Among other nervous symptoms exaggeration of the knee-jerk has been noted.

Marked and persistent tremor sometimes occurs, and is said by Donkin to point to a deep ulceration, a point much emphasized in typhoid of adults by W. G. Thompson. No lesions of meningitis were found in these cases, and cases resembling meningitis, which occur occasionally in hospitals and die, on autopsy, instead of the lesions of meningitis, frequently fail to show any change in the brain or membranes. The cases of acute maniacal delirium with high fever and rapidly fatal termination which at times occur, have no change in the tissues outside of the blood-vessels. That there has been some cause and some lesion is certain, but no exudation of serum, fibrin, or pulse, or even marked congestion, is to be found. There is left the probability either of temporary changes in the blood-vessels and circulation which have left no traces, or more probably, some very subtle delicate change that our usual methods of preparing brain specimens do not detect. As strychnine affects the cord centres, so, I believe, the ptomaïne of typhoid fever may affect the brain centres.

It may be asked, in view of these extensive nervous symptoms, how one can be certain that his case is not one of epidemic cerebral spinal meningitis, which may begin like typhoid, run many weeks with a rather similar course, with vomiting, hydrocephalic cry, rigidity of the neck, and opisthotonos, and all those meningeal symptoms mentioned, an indefinite eruption, and similar eye symptoms, strabismus, photophobia, inequality of pupils, and even blindness. The resemblance is certainly great, but the temperature curve is not characteristic, generally not over 102° F., and there is no regular evening rise. Pain in the back, limbs, calves, and thighs are more marked in the

epidemic meningitis. The eruption, if present, is more apt to be like herpes than a rose spot, as in typhoid. The pulse is almost invariably slow instead of rapid, and does not follow the variations of the temperature as in typhoid. There is apt to be a nasal catarrh, this being the method of entrance of the bacterial agent in the epidemic form, probably. Joint complications are also apt to occur.[1] The progress is constantly toward the fatal outcome, with paralysis, either hemi- or mono- or paraplegia, while in typhoid recovery is to be looked for in a fair proportion of cases.

Tubercular meningitis, like the epidemic form, resembles typhoid, but almost always has an antecedent tubercular trouble in some other organ, and a more gradual onset. The temperature is seldom high, averaging 101°, and reaching 102.5° only near the end. The vomiting is violent, frequent, and propulsive, and occurs without reference to food taken. Pulse slow and irregular. Respiration sighing, abdomen markedly boat-shaped, and the skin may develop an erythema. At first there are marked and severe brain symptoms without special "typhoid symptoms." Later a "typhoid state" is sometimes developed with a rapid pulse and diarrhœa that might be confusing if compared without knowledge of previous history. As a rule, the symptoms will be first those of a general meningeal irritation, then localized brain and meningeal irritation, and finally symptoms of absolute paralysis of different brain areas, becoming more and more complete until the vital centres are involved and death ensues.

We have laid stress on the low pulse in these two forms of meningitis. In typhoid the pulse should vary from 90 to 120, according to the height of the temperature. It has been observed from 152 to 180 and irregular, in cases that afterward recovered.

The heart is commonly affected more or less in typhoid in infants, and Donkin states that a modification of the first sound is generally found in most cases in the second week, and that observation of the radial pulse alone is not enough to show how the heart is working. In my case two very alarming spells of heart failure and collapse followed two very careful attempts to make an examination of the back of the chest. I cannot too much lay stress on the necessity of keeping the little patient continuously on the back, giving him the benefit of the doubt and avoiding any risk from extensive physical examinations, however careful, extensive bathing, or any unnecessary changing of the position. Let objective symptoms give information of any new condition developing in the lungs, always remembering that both lobar pneumonia and broncho-pneumonia are rare complications. Hypostatic pneumonia or œdema of the lungs must be looked out for and avoided by the treatment if possible. Nephritis or other urinary symptoms are rare.

The duration of the disease is variable. In 190 cases of Henoch, 11 terminated between the seventh and ninth day; 36 cases between the tenth and twelfth, inclusive; 45 between thirteenth and fifteenth; 40 between sixteenth and eighteenth; 25 between eighteenth and nineteenth day; 39 between twentieth and twenty-third day; 14 between twenty fourth and thirtieth; 6 between the thirty-fifth and forty-fifth day.

Collapse and sudden death are rare except in the graver cases, and owing to the less extensive lesion in the intestines many children do well.

In treatment a conservative course will commend itself. Tub-baths will not be well borne in most cases, though sponging rather than antipyretics will best bring down the temperature. The task of choosing a food that will be digested and leave no undigested masses in the stools, is very difficult, but must be very carefully studied and watched, or there will be trouble. Brown suggests constant under-feeding, or a starvation treatment. A mineral acid and a little bismuth may be all the drugs needed in favorable cases, in others bromides or other mild sedatives for the nervous symptoms, and drugs by rectum rather than by the mouth if there is constipation, will be valuable. For the heart symptoms, frequently repeated doses of champagne were found exceedingly valuable, and were well taken by the patient. Diffusible stimulants, like ammonia and camphor, were quite as effective as the more powerful ones, digitalis, strychnine, or sparteine, though all were tried in appropriate doses at certain times. Heat over abdomen, and high hot enemas, were always prompt and efficient means of counteracting collapse until the last. In a very severe collapse with cyanosis, fluttering feeble pulse, and failing respiration, when all other heart stimulants, including oxygen and electricity, had failed, at the suggestion of Dr. Whitehorne a combination of spirits of camphor, aromatic spirits of ammonia, tincture of musk, and the normal liquid of nitro-glycerine, of each one minim, dropped on the tongue with a medicine dropper, was followed by a change from what had been almost a moribund condition to restoration of life, fair pulse, and a favorable condition for half a day. The preparation was absorbed from the mouth and acted quite as promptly as a hypodermic and with far less shock and irritation to the infant. In an experience with cases of collapse and shock by no means small, the writer has never seen such a prompt reaction from so desperate a condition.

Two other suggestions will be made as a result of the study of these cases: 1. Sterilize or Pasteurize all milk used for young children, and boil all water during the early years. 2. In all cases of a diarrhœal nature in children, disinfect the stools—a measure indicated if it is only a simple summer diarrhœa, since the more recent studies in its bacterial origin and doubly indicated from the possibility always present that these cases may be irregular or hidden typhoid fever.

VARIX OF THE RIGHT AURICLE ENDING IN RUPTURE.

By WM. G. SMITH, M.D.,

STURGIS, SOUTH DAKOTA.

Considering the rarity of the above-named affection and the interesting features of its development, I will detail the progress of the disease as it developed in a patient under my care.

Louis L——, of French Canadian parentage, born at Quebec, aged fifty-six, and by occupation a teamster, a married man although not living with his wife for several years prior to his last sickness.

Mr. L—— gives a history of having the diseases of childhood with no ill effects following the same. He was an excessive tobacco user and an excessively hard drinker in former years. He denies any venereal trouble and no history of any hereditary disease in ancestors can be elicited.

The above disease commenced on June 12, 1889, while Mr. L—— was making a trip from Sturgis to Deadwood, S. D., on a rainy day when the roads were very muddy. His wagon broke down, which compelled him to do some very heavy lifting. After one strenuous effort he was suddenly taken with acute pain and oppression in the mid-sternal region. He continued his trip to Deadwood and sought advice, as the pain was very severe and as he was at the same time suffering from the effects of a cold. Treatment consisted of cough mixtures, anodynes, and counter-irritations.

On the following 16th of June he wrote me to send him some medicine for pain in the chest and a cold. I prescribed an expectorant mixture containing an anodyne, and advised his return to Sturgis if he did not soon get relief, so I could make an examination.

Some three days later he reported at my office, still suffering from the acute pain in the chest. I made a careful examination and found the acute pain located over the region of the right auricle but somewhat diffused in area. I could find no increased dulness on percussion. The heart beating was rapid and tumultuous, the pulse at the wrist was compressible, and the artery gave

somewhat of a cord-like feel, and the sensation of high tension or blood pressure.

The urine was normal in every respect. There was some oppression in the chest and slight dyspnœa, which I took to be of nervous origin due to tumultuous heart action. I was unable to be positive in my diagnosis, and treated on the symptomatic plan. Gave a hydragogue cathartic with the effect of lowering blood-pressure and unloading the bowels. Gave fluid extract of digitalis to quiet tumultuous heart beating, and an anodyne, as the pain showed great obstinacy while upon the above treatment.

I was not satisfied, and upon further examination and meditation I came to the conclusion that the exertion had produced a strain on the aorta; and fearing aneurism, I put my patient on iodide of potash and Squibb's fluid extract of ergot, informing him that he would likely be sick some time, and instructed him to drink as little of liquids as possible, not to overload the stomach, desiring in this way to keep the blood-pressure as low as possible. Also advised him to avoid mental excitement and physical exertion.

I was favored in a few days by the pain's decreasing, the faintness and dyspnœa disappearing, and in four weeks' time my patient felt in his usual good health and resumed his ordinary occupation. The result caused me the more to doubt my fear of aneurism and left the real nature of the disease in obscurity, for previous to this sickness my patient had always been very robust and possessed an iron constitution, so to speak.

A year later, in June, 1890, Mr. L——, for the first time since his previous treatment, returned to my office complaining of the same old pain and oppression in the chest, which he said had been troubling him for the last three or four days. The pain was so severe that I gave him an opiate, and instructed him to return for an examination as soon as he was easier and able to lie quietly. He did so, and upon this examination I found cardiac dulness slightly increased tranversely to the right. Heart action was slower, numbering fifty-six pulsations to the minute, and temperature was normal. There was, however, an increased shock to the impulse beat.

Remembering my former inclination to believe in aneurism I carefully examined, but could get no bruit. I could get no distinct dulness separate and distinct from that of the heart. I could detect what I took to be a tendency to atheroma and I proceeded to my diagnosis by the exclusion method; but was unable to entirely exclude aneurism, and still I was unable to make a positive diagnosis of it, but inclined to that disease, and again commenced my former treatment of iodide of potash and Squibb's ergot, instructing my patient to avoid all alcoholic beverages, to refrain as much as possible from the use of tobacco, to limit his use of liquids, to avoid overloading his stomach and to avoid mental excitement and physical exertion.

I gave cascara sagrada for the bowels, which were constipated, a condition which I must say was very rare, for the regularity of the bowels was very marked even when opiates had to be administered.

During the later part of July, 1890, I thought I detected slight evidence of bulging of the thorax in the mid-sternum region. The apex beat at this time was one inch to the right of left nipple and three-fourths of an inch below a line passing through both nipples.

Auscultation gave negative results, as nothing abnormal could be detected except the increased cardiac force. There was no jugular pulsation, as frequently occurs in tricuspid regurgitation or dilated right ventricle, no buzzing in the ears, no vertigo, but a slight tendency to syncope and a slow pulse, ranging as a rule from fifty-six to sixty to the minute.

This time the pain, weakness, syncope, and oppression did not respond so quickly to treatment, and an occasional opiate had to be administered.

About this time a travelling doctor from Omaha was making monthly visits to the Black Hills and took in Sturgis. The unrest that is so liable to overtake a sick person troubled my patient, and he began to want to know how long it would take him to get well. I told him that in my opinion he would not be able to resume work during the summer. This made Mr. L—— all the more want to try Dr. P——, who was advertising quick cures, no cure no pay. Finally Mr. L—— went to see the doctor, who, the patient said, would agree to cure him for $10 in advance. Mr. L—— offered to put in the bank the $10 subject to the doctor's order in case of cure, but this proposition was not accepted.

My patient did not improve as fast as he thought he ought to under my treatment, and later put himself under the care of Edward J. Sexton, a regular practising physician of ability. In talking the case over later with Dr. Sexton he kindly informed me that his first diagnosis was dilatation of the left ventricle, and he treated him for such; but upon a re-examination he changed his diagnosis to aortic aneurism, and treated him accordingly. The doctor informed me that the pain was so severe and rebellious that he had tried all the anodynes, and the only relief, which was partial, was from morphia.

The disease gradually progressed, the patient being able to walk about, until October, 1891, when he was stricken down with hemiplegia of the left side, lying for several days very near death's door, while stopping with friends in the country.

In January, 1892, Mr. L—— was removed to Sturgis, and as his means of support had been exhausted he became a county charge, and again came under my care, I being the county physician. At this time he was still suffering from hemiplegia, although somewhat improved and able to be up. I put him on tonics containing phosphorus and strychnia, and also made tri weekly applications of faradism, which improved the muscular action.

An examination at this time showed more marked bulging in the right auricular region, and increased dulness, which extended farther to the right. The apex beat was marked and increased in force. There was dyspnœa and a dry senseless hacking cough present. The second heart-sound seemed slightly accentuated; a faint-like feeling was complained of, and the pain, which was described as piercing, tearing, burning, aching, and wearing in character always at the seat of the bulging, passing posteriorly to the upper interscapular region, most marked at the left of the spine, was the most severe symptom, although remitting at intervals, and then returning with increased vigor.

I could detect no murmurs, no jugular pulsation, no bruit, no irregularity in heart's rhythm, no intermittency in heart's beating, no dulness separate and distinct from that of the heart, and no inequality in radial pulses. There was, however, an increased cord-like feeling in radial arteries, and the anterior convex portion of the bulging in the chest was softening, and a pulsating beat was plainly felt on palpation, which gave the impression of transmitted shock and some interference, with vesicular murmurs at apices of both lungs.

Although still uncertain I felt quite positive the disease was aneurism of the aorta, and at that portion beyond the point of the origin of the left subclavian artery, for the reason that there was no inequality in radial pulse. I again resorted to drachm doses of Squibb's fluid extract of ergot with scruple doses of iodide of potash three times a day.

My patient being indisposed sufficiently to keep him in bed, I could see a slight diminishing in the size of the bulging, which I took to be the result of medication; but in a few weeks he regained his appetite and strength enough to be up, and no amount of argument or persuasion would make him keep quiet, and as soon as he began to walk about the bulging began again to increase.

As before stated the severe pain was the most troublesome symptom I had to deal with, and I found that any drug that lowered the arterial tension gave temporary relief. On one occasion my patient came into my office

nearly wild with pain. I had him lie down on the lounge and gave him one minim of nitrite of amyl, and was surprised at the instant relief of the pain. Seeing the quick results, I prescribed a mixture of nitrite of amyl and fluid extract of prun. virg., and for some time it acted admirably; later I also tried glonoin, but it did not act as well as the nitrite of amyl. At a glance one will readily see that the nitrite of amyl antagonized the effect of the ergot so far as it affected the arterial tension, and recognizing this fact my first dose was an experimental one.

In treating the pain I resorted to various anodynes and somniferous drugs, frequently without avail, and had occasionally to return to morphia either by mouth or hypodermically.

I always advised the taking of small amounts of liquids, the avoidance of stimulants, restricted diet so as not to overload the stomach, and thereby mechanically increase the pressure, avoidance of mental excitement and physical exertion.

The bulging gradually increased until no trace of rib or cartilage could be detected by palpation at the seat of bulging, and the walls of the sac became adherent with the anterior chest-walls so intimately that, in making the dissection after death, there appeared no division between the auricular sac and the chest-wall, and the pulsation of the local bulging could be easily seen several feet distant.

Palpation gave the impression of transmitted shock. As the disease advanced the dyspnœa became more marked, due, in my opinion, to the pressure causing imperfect pulmonary circulation and deficient aëration of blood.

There was, at times, slight inequality of the pupils, never well marked. Patient suffered also from an occasional headache. The cardiac dulness gradually increased to the right and the respiration became more laborious as the pressure increased.

There was at no time any dropsy, no inequality of radial pulse, and the cyanosis was slight.

Photograph, Figure 1, was taken early in July,

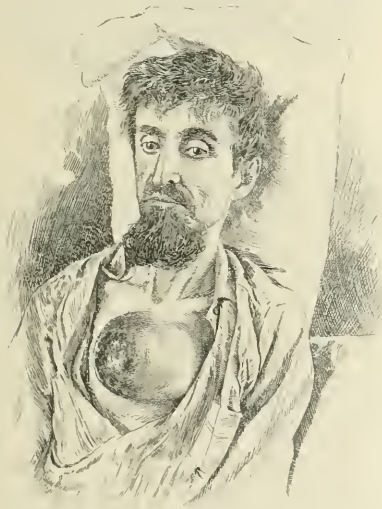

Fig. 1.

1892. In the condition here represented the patient would occasionally have two or three days at a time comparatively free from pain, and then again it would come on in the severest manner, extending to the left shoulder and down the left arm to the finger tips, similar in character to the subjective symptoms in disease of the cardiac valves.

During the last week in July I was called away for a few days, and I had Dr. Ira L. Sanderson, of Sturgis, a physician and surgeon of long experience, formerly of the United States army, attend my patient, as frequently hypodermic injection of morphia had to be administered to allay the pain. After my return Dr. Sanderson informed me that he considered the case as one of aneurism of the aorta.

I continued iodide of potash and ergot for the reason that I thought I had an aneurism to deal with and knew of no better medication. About this time difficulty in swallowing food developed, and the above symptoms continued, gradually increasing in severity.

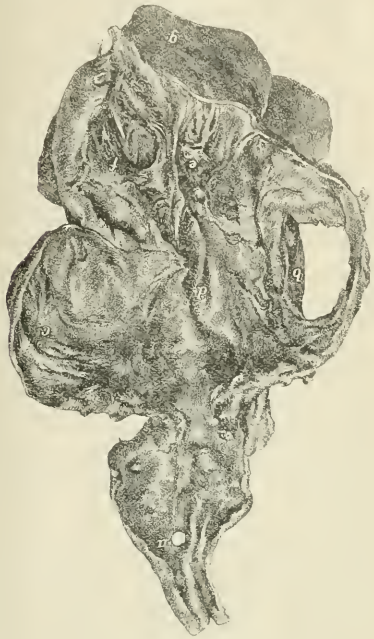

Fig. 2.—Organ laid Open.

In this you can readily see the disease has made greater strides. During the last two months superficial ulceration has already commenced in that portion nearest the right nipple, and its development progressed rapidly considering that only ten days had elapsed since the ulceration commenced.

During this process of ulceration the patient had no rest night or day, morphia having no effect in ordinary doses, and the hypodermic injections were increased up to two grains per dose, and repeated every hour for three doses the day before he died, as rupture seemed possible at any minute and humanity demanded some relief, but sleep was not produced. At my last visit, the day before his death, October 7, 1892, Theodore Haas, a druggist, accompanied me, it being near midnight. I had previously covered up the ulcerated portion of the bulging with a piece of lint smeared over with carbolized vaseline and gave instructions that it should not be removed, but my patient's curiosity became uncontrollable, and while my back was turned he removed the lint, and suggested more vaseline. While applying more vaseline to the lint I heard him cry out, "I am bleeding to death." Mr. Haas had just previously noticed him remove a black object, which was a clot of blood, which acted as a plug in one of the ulcerated holes, and when removed allowed the blood to flow out freely, which it did, spurting probably some two feet for a moment and then gradually lessening its expulsive force.

The blood was venous in character and more regular

in flow than it would have been had the blood been arterial. In half a minute or less another clot filled the opening.

My visits were very frequent during the last few days of his life, and I was at his bedside a few moments before his death, which occurred at noon on October 8, and it was with great difficulty that he swallowed even liquids for the last few days of his life. Death really resulted from inanition, as his inability to eat food had caused marked debility and excessive anæmia.

Thus ends the case of our supposed aneurism of the aorta, and a hasty review of the subjective and objective symptoms, which have been misleading, in which the underlying etiological factors produce appearances not especially peculiar to it, but common to a frequent and well known affection of the blood-vessels, we can usually see wherein our error lay, before we detail the results of the post-mortem examination perhaps would not be amiss.

As in aneurism (intrathoracic) we had pain in chest, even extending to shoulder and down left arm to fingers, and here I would quote from Dr. Walshe, who says, "The absence of symptoms and signs indicative of ordinary affections of the heart and lungs in an individual suffering from persistent anomalous disturbance within the chest, even although he does not exhibit any failure of general health, affords strong motive for suspecting aneurism."

We have in our case the disturbance in the chest spoken of, we have failure of general health, we have dyspnœa, we have some inequality in the pupil, not marked; we have laborious respiration with disturbance in vesicular murmur, we have difficulty in swallowing, we have the hacking senseless cough, although no paralysis of either pharyngeal nerve; we have evidence of atheroma, as shown by hemiplegia; we have a pulsating or heaving expansile tumor, although not distinct from that of the heart; while, on the other hand, we cannot detect any systolic bruit, which is often absent in aneurism. We cannot detect separate and distinct dulness from that of the heart, we cannot detect any inequality in radial pulse.

My mistake in diagnosis was due to a lack of proper consideration being given to the heaving expansile impulse of the pulsating tumor, which was not distinct from that of the heart, and in my case misled me by giving the impression, by palpation, of transmitted impulse, which condition was caused by the expansile impulse being interfered with by the interstitial inflammation, which caused an adhesion of the sacculated portion of the heart to the internal anterior wall of the chest, thereby causing a lessened elasticity, lessening the expansile thrust and producing with the impulse of the tumor a tendency to shock.

I am aware that diagnosis of sacculated ruptures of the heart's cavities, or as some prefer to call them "heart aneurisms" or "heart varices," are frequently not made until the patient reaches the post-mortem table; but nevertheless I now consider this expansile impulse, with a seeming tendency to transmitted shock, very diagnostic of a sacculated rupture of one of the heart's cavities, when its dulness is not distinct and separate from that of the heart's dulness.

One other conclusion I shall draw, and that is in reference to the pain. In aneurism the pain is more frequently first complained of in the shoulder or passing down the arm to the hand, while in sacculated heart cavities, as in valvular disease of the heart, the pain is more frequently first complained of in the cardiac region and then radiates to the shoulder and then down the arm.

We will now look at the heart as it appeared on being removed from the body as shown by photo marked Figure 3. Letter *a* represents aorta; *b*, left innominate artery; *c*, the sacculated portion of the right auricle as represented in Figure 2, by the bulging in the chest; *d*, the right auricle; and *e*, the heart's apex.

Viewing the heart as it is laid open, as represented by photo marked Figure 2. *a* represents aorta laid open; *d*, the left auricle; and *c*, the posterior wall of the right auricle; and the letter *b* intended to represent the anterior wall of the right auricle, and the rupture or hole in the same. Letters *e* and *f* represent the ventricles; and *l*, the apex of the heart.

We find the aorta dilated, so also the auricles; but more marked in the right. There is dilatation of superior vena cava, but not excessive.

Upon examination of the sacculated right auricle from a pathological point of view, I am of the opinion that the disease originated in a local circumscribed fibroid condition of the inner surface of the anterior wall of the auricular chamber, which resulted in new cellular growth, thereby producing interstitial pressure on the muscular fibres causing or resulting in fatty degeneration. There is no doubt but that the whole thickness of the anterior wall of the right auricle at the seat of the disease was affected and the muscular fibres degenerated.

The localized sacculated portion of the auricle, the seat of the fibrosis, presented a glistening fibrous appearance, of a dirty white or nearly grayish color. I believe the fatty degeneration exceeded the development of fibrous

FIG. 3.—Appearance on Removal.

tissue, and as a result the affected circumscribed area softened and thinned at the same time and in this manner the bulging took place.

The fatty degeneration could easily be detected by palpation and inspection, for it presented a greasy feeling even after the specimen had been in alcohol several weeks, as well as a greasy aspect. The fat had increased considerably, but more markedly so in the inner layer of the sac, as manifested by the increased number of oil cells, as shown by examination with the microscope, and every condition present suggested that the limited area of the sac, as represented by the letter *b*, was intensely and uniformly affected, though sharply defined or limited. This limited circumscribed spot was circular, but presents a more elliptical form in photo, caused by the position in which it was held while being photographed.

As a usual rule the ventricles are more often affected than the auricles; indeed some authors doubt that the auricles are ever affected. They are certainly occasionally the seat of fibroid degeneration and their walls may be affected in a limited area, which is sharply defined, and through the entire thickness of the walls, as illustrated in the case before us.

In primary rupture of the heart the immediate cause of the tear is probably an unnatural, excessively energetic contraction of the heart, producing a greater strain upon the fibres than their degenerated condition can resist. This condition of energetic contraction can be brought

about by excessive lifting, straining, or perhaps a violent coughing.

This condition, as can readily be seen, would most often affect the ventricles, as the greater blood tension would there exist during such efforts; but I take it that in a localized, sharply defined, circumscribed fibroid condition, succeeded by fatty degeneration in the auricle in our case, the force being less than in the ventricle, there would be less liability to rupture, or a complete tear through the wall; but the weakened part would partially give way, and in time, considerably longer than in case of the ventricle, a sacculated condition would form, gradually distending, and through pressure on adjacent organs the various symptoms, as in the case before us, would be produced.

As Jenner pointed out, congestion of the walls of the heart is a cause of fatty degeneration of the muscular fibres; but this degeneration is rarely simple—more or less fibroid growth is usually conjoined. In the present case the cause of the fatty degeneration is probably alcoholism, the same being the cause of the atheromatous condition, and I take it as the probable cause of the fibrosis, augmented, perhaps, by the tobacco habit.

In fatty degeneration we expect to find diminished force of impulse and a weak apex beat, together with enfeebled heart action; but in the present case we find the very opposite condition, and I account for this by the fact that our limited area of degenerated muscular fibres was in the auricle, and even in forcible heart action the tension was not sufficient to complete rupture, and not sufficient even to prevent regular ventricular contractions, which have more to do with impulse and apex-beat, when the muscular fibres of the ventricles are not degenerated, than do the auricles.

The energetic effort at lifting, at the first appearance of pain, was probably the immediate cause of affecting the diseased auricle, and no doubt resulted in an injury to the diseased area, thus producing inflammation and local congestion and allowing every excessive increase in blood-pressure to add to the mischief already existing, which gradually progressed until the results as portrayed by the photographs finally developed.

CRIMINAL ABORTION.

Its Evils and Its Sad Consequences.

By MARY A. DIXON-JONES, M.D.,

NEW YORK.

In law the term abortion is applied to the expulsion of the fœtus at any period of pregnancy before the term of gestation is completed.

Abortion, induced at any time, or for any purpose except for the mother's welfare, or for the preservation of the life of the fœtus, is a crime and a murder. This foul taking off has been the cause of the destruction of an uncounted number of children; and has, in unnumbered instances, resulted in the death or ill health of the mother.

Under these two heads I will briefly discuss a few phases of the subject: First, the danger to the mother; second, loss of infant life; and third, as further developing the thought, will give instances of women who have sought to have abortion produced; and finally, will refer to the medico legal aspects of the subject.

As soon as conception takes place the vital forces are summoned to new energies and new activities dormant powers are aroused, and wonderful processes commence. The uterus and whole organism begin preparing for the great work, the growth and development of a human being, to be perfected in the short space of nine months. To interrupt these processes is a shock—a shock to the whole being, the nutritive, nervous, and mental systems; it does violence to the procreative organs, and renders them incapable of ever as efficiently performing their special functions. Subinvolution cannot take place as in the normal termination of pregnancy. This gives rise to multiplied evils, the full significance of which are, as yet, not fully understood. The uterus and its adnexæ, especially, suffer in many respects, swelling from the increase of living matter; then follow enlargement, hyperplasia, various misplacements, inflammations, and fibrous degenerations; in some cases, cancer or malignant growth is the natural outcome; in all, there will result some trouble that, for years, may give distress, suffering, and lasting weakness. Women may not at first show the full sad effects, may even, after repeated abortions, apparently do well; but, though not recognized, grave consequences always follow, resulting ofttimes in disease that may become more and more complicated, more and more dangerous, many times terminating fatally; and always, to some extent, shortening life. Many strong, healthy women have, by it, been made invalids for life, and to it many date the commencement of their sufferings and their continued ill health. Thomas says:[1] "That this criminal practice constitutes a prolific source of uterine disease, no one engaged in gynecology can for a moment doubt." Even the sepsis that is apt to follow may cause rapidly fatal peritonitis, or may induce an incurable disease of the uterine appendages, which is not only a cause of much suffering and ill health, but ofttimes eventuates in subsequent and absolute sterility. Septic inflammation most frequently destroys all functional capability of these organs; and in connection with this I dare assert, and believe the fact can be fully substantiated, infinitely more women have been made sterile by sepsis introduced at abortion, or even ordinary labor, than results from all the cases of removal of the uterine appendages; and this disproportion is vastly increased by noting the fact that in most of the cases where the diseased uterine appendages have been removed, the individuals had previously been rendered sterile by the disease of the named organs. I have known repeated instances where young married women, even in their first confinement, have by some sepsis been forever deprived of the privilege of subsequent maternity, have by this sepsis been made permanently sterile. I have known such repeated and sad instances of this, and so impressed have I been with the fact that I said in an article in the *New York Medical Journal*,[2] that "an obstetrician should be an antiseptic surgeon." As illustration and proof of this we have only to refer to the brilliant obstetric work of many of our great antiseptic surgeons. James Murphy, in his late address before the Section of Obstetrics, at the Annual Meeting of the British Medical Association,[3] said: "Puerperal septicæmia is the most fatal disease that childbearing women are exposed to, and though its frequency has been discussed of late, its fatality has, I fear, been but a little, if at all, reduced."

But immediately fatal results ofttimes eventuate from the attempt to produce criminal abortion; the shock, unexpected injury, uncontrollable hemorrhage—all make a sad record in this horrible work. The coarse brutality that will allow one to engage in it, is necessarily accompanied by more or less unskilfulness, that shows in every detail a lack of scientific refinement and natural delicacy. In the *American Journal of Obstetrics*[4] Dr. Hektoen, of Chicago, reports a case of an abortion, produced by a "Dr. S.," at the fourth month of pregnancy; "the insertion of a rubber catheter, its disappearance, rupture of the uterus, eventeration of the large intestines, and immediate death." It also states that the operator, "Dr. S.," had even pulled on the supposed placental cord, and that the patient herself had taken hold and pulled with all her power, "in order to expedite matters!" Two lives were thus sacrificed.

Dr. Hektoen, in the same article, gives another instance of an abortion at the fourth month, also resulting in rupture of the uterus and death. In the *Pittsburgh*

[4] July, 1892, p. 69.

Medical Review[1] there is reported a smilar case of rupture of the uterus from an attempted abortion, followed by immediate death. The *Cincinnati Lancet and Clinic*[2] reports a case of rupture of uterus and death. The *Journal d'Accouchement*[3] reports the case of "a woman, six weeks pregnant; death followed almost immediately from the attempt to introduce an instrument into the generative organs." Oskar Sattler reports tetanus as following a similar attempt. Stephen Crowe, of Baltimore,[4] reports the case of "a woman three months advanced in pregnancy. A tent was introduced; in the attempt to remove it it was broken, and three quarters remained in the uterus. The patient was removed to the Maryland General Hospital; temperature, 103° F.; pulse, 140; abdomen enormously swollen."

Dr. E. J. Ill[5] says: "A knitting-needle was in one instance forced through Douglas's cul de sac and the mesentery into the liver, to the depth of an inch, which was found after her death." He also tells the case of a "crochet needle, which passed through the fundus into the peritoneal cavity." The *Australian Medical Journal*[6] states that "within a week four women, in the prime of life, met death by the forcible introduction of an instrument into and through the walls of the gravid uterus." Eight lives were sacrificed. J. Phillips[7] reports "a patient dying from injection of nitrate of mercury into the vagina to procure abortion." In the *Albany Medical Annals*[8] there is reported "an attempt to blow air into a uterus three months pregnant, the woman fell over unconscious, and expired a half-hour later."

The *Boston Medical and Surgical Journal*[9] reports the case of instant death from "an attempt at criminal abortion on a strong, healthy woman, in the seventh month of pregnancy, air being forcibly injected into the uterus, causing instantaneous death." The inter-uterine douche may have detached a portion of the placenta, so that the air entered the circulation through the opened uterine sinuses, forming an air embolism. The entrance of air into the blood-vessels has frequently in these attempts caused instant death.

In many ways the effort to produce abortion may be immediately fatal. The newspapers of every city teem with reports of such ghastly deaths. Many may be unknown and unrecorded, but women hasten on. Many of them are like the daughter of the pious old sexton, of New York; healthy, young, and full of life, she entered the operator's office; he promised immediate relief, she never came out alive. The double crime was perpetrated. Uncounted millions of unborn infants have thus perished. There is no darker page in history. The extent and fearfulness of this work is not known or recognized, and cannot be measured. Those who engage in the traffic certainly do not comprehend its full import, or understand the deep, dark iniquity of their deeds. No words can depict its horrors or its terrible risks. It always destroys the life of one human being, and possibly a second; or, at least, may make a wreck of the poor misguided woman.

Statistics state that in New York City there are annually twelve or thirteen hundred of still-births. Probably half of the still-births are from induced abortion. In fifty years this would amount to over thirty thousand; and counting other cities of the Union, there would be hundreds of thousands more. But even these numbers are as nothing compared to the millions of "silent" births that are constantly being produced in the earlier months of pregnancy. As a mother said a few days ago, "I have missed twice, but I am going to bring my courses on." Thousands of thoughtless women are doing the same thing; and there are unnumbered "professionals" at hand to help. The *British Medical Journal*[1] gives the name of an old man, "Hippolyte Terle, who confessed to having practised it for years," and this man acknowledged that he "could not tell the number of times he had committed the murder," probably almost countless. The same journal[2] gives the name of another prisoner for the same crime, one "Elizabeth Topham;" nor could she tell the number of times she had produced illegal abortion. Well did Professor T. G. Thomas, in his excellent work, say:[3] "Statistics showing the frequency of criminal abortion never have been, and never will be, written." There are thousands engaged in the work, reaping their rich harvests; and, at the same time, making a harvest of deaths. But the most deplorable fact is, that there are a multitude of mothers willing to assist, or, doing it continually. Who can tell the number of infant deaths? A holocaust —a great army of little children are destroyed. The loss of infant life is amazing.

But, if possible, there is yet a greater evil. The woman who entertains such thoughts, who has such intentions, the mother who thus seeks the destruction of her own child, thereby perjures and blackens her own soul, and demoralizes her whole moral being. It is a prostitution of all her higher nature. To think of a mother contemplating the murder of her own child! studying to destroy the being that rests nearest to her own life, and bound to her by every tie of kindred, love, and interest. What a soul-staining! Could anything be more debasing and blunting of all the finer feelings and affections? She who in secret broods over such thoughts, who has such intentions, is making of that child and of her children murderers. The child must take on the then condition of the parents, moral and physical. It is as much a part and parcel of the parent as is the lower order of animals, where procreation is by subdivision. I could imagine that he who is guilty of signal crimes and murderous intents is born of such a woman—a woman who for days was trying to compass his murder, and was seeking opportunities to do it secretly and successfully.

What reason do women give for so doing? Some say, "It is inconvenient to have a child!" It should be their greatest happiness. Others say, "They have too much to do, too many claims upon them, the demands of society, fashion,' etc. But this is their first duty, and should be nearest and dearest to them. Others say, "A child is too much trouble." Ah! an infinite source of delight should the care of her little one be to any true mother. Others again declare "they have not the means to support it," or that "they want, for a while longer, to take their pleasure," "at some more convenient season," say they. A burglar who takes a man's life wants the money, because work is inconvenient, he has so many demands upon him, and this may relieve him from care and trouble, and enable him, a while longer, to take his pleasure.

There is more similarity between the two than we dare trace out. Women are not taught to understand these things, they are not sufficiently instructed as to the wonders of their own being, or even of the simplest laws of life and health. They do not sufficiently know the great mysteries and beauties of life, that from the moment of conception a child begins to live, that as soon as there is a combination of the two elements, it is a human being. If not then, will anyone say when life begins, at what time the soul meets the body? I maintain that the destruction of this new being, even in the earlier periods of existence, is as much murder as it would be in the latter months of pregnancy, or in the earlier periods of infancy. I hold that it is as much murder to destroy a child that will be born next May as one that was born last May. Some have asserted there is no life till it moves, or what is understood as the "period of quickening." At the first moment there is

motion, and there is motion every moment of its existence. The new being unceasingly moves, and the powers, processes, and changes, even at this early period, are marvellous. It is then a human being. To destroy it is worse than vandalism. To attack it thus, in the dark borders of its existence, in the vestibule of its being, when it is so helpless and defenceless, is a most cruel warfare, a most unfair battle, more cowardly than the midnight assassin, or he who puts the dagger in the heart of the unsuspecting. But it is not the "dark borders of existence." It is holy ground. Eternal Wisdom is there at work. "He formed us in the depths." "Our substance was not hid from Him." "He breathed into us the breath of life." From the first it is a living soul, endowed with vast capabilities and possibilities. It has work in life to do, and an eternal destiny. Have we a right to deprive it of its future possibilities, and opportunities of fulfilling its high mission? Shall their unborn spirits go to Him, and say they were not allowed to accomplish their allotted work? What if the mother of Washington, of Shakespeare, of Lincoln, or of Milton had so acted? In eternal light there will be just as sad reckoning, in every case. A sin so terrible brings its full and increasing evil, with arithmetical progression. The responsibility is not all in the simple act, it carries a weight beyond. Are those who help women to do this deed any less to blame? Is not their work the blackness of darkness, by whomsoever performed?

In 1879 Mrs. G——,[1] the mother of children and the wife of a prosperous business man, called at my office. She was then twenty-eight years old; married six years, had three children, and one miscarriage. She stated that she had found herself again pregnant, and wanted "to get clear of it;" also said that her miscarriage was brought on by her physician replacing the womb, adding: "My doctor knows that I am now pregnant, but he does not think I can carry it, and that it would be just as well to bring it away now. He has been trying, and gave me aloes, told me half a teaspoonful was the dose, but if I would take three it would make it all the surer."

Here a woman of some wealth, position, and a church member, deliberately comes and asks me to help her to destroy her unborn child, saying, "She is not going to have it, because she has too much to do." Murder was in her heart. While I had the most intense disgust and indignation, I quietly told the poor woman she ought to be thankful and feel honored that another member was to be added to her household, that nothing was more lovely or interesting than a large family of children. She coldly and cruelly replied: "I am not going to have this child, and my family physician has been giving me pills to enable me to get clear of it." She gave me his name, I warned her of the danger, urged her to desist, and asked her if she had any more right to destroy that child than any other member of her household. The woman went home; I feared my word would not sufficiently impress her, so the next day I wrote her, emphasizing the same thoughts. The child was allowed to live. He is now a big boy, attending school. I have seen him many a time, but how near he came to destruction! and probably he will never be as finely constituted as if his mother had not brooded over and contemplated so heartlessly her own boy's murder. When will mothers look into these things and understand.

In 1866 a mother called to see me, wanting then to get rid of her unborn babe, saying that "she had three children, and her husband was not able to support any more." I inquired if she was not willing to share her little with this one also. I presented many considerations. She heeded nothing, but, with cold selfishness, seemed determined on her child's murder. I gave her more serious words of warning. She went I knew not whither. This woman was more cruel than the Hindoo mother who throws her child into the Ganges.

[1] All the circumstances here narrated are facts. Names will not be mentioned, whether the parties live in Maine or Mexico. The facts belong to me, and are accurately stated.

One day, more than twenty years ago, I was called to see a sick patient. It was a home of comfort and plenty. The young woman, scarce eighteen years old, lay in her bed; she was a delicate, feeble girl. By her bedside stood the mother, a refined, elegant woman. The mother simply called my attention to her sick daughter, that she was not regular, and that she wanted "her courses brought on." My duty was to find the cause of this retention. Examination showed that the patient was two months pregnant, and my first inquiry was how long she had been married. This revealed all. The mother, in her deep grief, told the tale of sorrow, of the daughter's engagement, and the man had gone!

This read a whole lecture as to a mother's duties and her watchful care, and how she should instruct her daughters in all that is right, and show them the beautiful side of life. The mother exclaimed: "This must be got away." "But," said I, "the daughter must now do what is right. She cannot destroy the being to whom she has given life." "Ah," said the mother, "death before dishonor; my daughter is not going to be disgraced all her days, and the man go scot-free." I reminded the mother again that it was a living child, and that to destroy it would be murder; and besides, would imperil her own daughter's life.

I left them in their grief. The next day the father saw me, said "he knew of my removing successfully a tumor from the womb of a lady who was a friend of his wife, and that I could do this just as safely." "That," said I, "was done to save life; you ask me to destroy life, possibly two lives." He offered a price! "No," said I, "not for this city full of gold, nor for ten million cities besides, would I take the guilt of murder on my soul." Notwithstanding all my warnings they found someone to do the dark deed. It was done in some way or somehow. Years after I met this young woman. She was an invalid. She married, but no babe ever came to bless that wedlock. She had to think of the pearl, the priceless jewel, that she had thrown from her, and that she had destroyed her own child! If young girls were instructed, if they understood, they would be far from such work.

In 18— a young lady called at my office. She was the only daughter of a prosperous merchant, for whose household I had been the family physician for more than a dozen years. I listened to her sad story—engaged to be married—one false step! I advised her if she loved the man to marry him, but to go first to her mother for counsel and instruction. She did both, the child was saved, and the daughter's life was spared.

In 1878 a young girl of education and intelligence called. She was pregnant and her affianced gone! When will girls learn to do right, and when will their mothers instruct them in all things. The principles of moral rectitude, planted deep, would deter from such conduct. If conscience or delicacy does not restrain, they might remind themselves of the startling tragedy of the king's daughter: "The hatred wherewith Amnon, the betrayer, hated her was greater than the love wherewith he had loved her." I advised this young girl, she trusted me, the child lived, and she thus saved her own health and strength, and had not the sin of murder on her soul. She must think of the rest.

A few years after, a grief-stricken one called on me as a physician to tell her tale of woe. I was more than grieved that she and others so little understood me as to imagine that I could or would help in such nefarious work. I attempted to give her light and advice. Two days after, the marriage rites were solemnized.

Another in like circumstances. I gave her the same counsel and advice, both child and mother were saved; but what a history of remorse and self-condemnation.

For the young unmarried girls there might possibly be some forbearance, some sympathy for them, in their desperation and misery. They are led on, deceived by false promises; they trust, and are left in desolation and bewilderment; they fly anywhere, anywhither for help or refuge;

but married women, what excuse have they? For them there is the most utter condemnation and execration.

In 1885, during the month of December, a married woman, Mrs. C——, called at my office, elegantly and expensively dressed. She informed me that she was then in the third or fourth month of pregnancy, and expressed her determination to get clear of the child, saying that she had suffered so much, had been sick since her last confinement, nine years previously, at which time she was ill in bed many weeks with high fever; on the eleventh day was not able to turn her head, and since that time the distress in her pelvis had continued, especially on the left side. She said further, "I do not want this child, it is an unwelcome visitor, and I will get clear of it. I have taken ergot by the quart, and have pills from the physician; he says he can help me, but as I have to go in the cars it might endanger my life." I explained to this woman the danger of such attempts, that it was almost sure destruction to her own health, that nothing was more disastrous than expelling prematurely the fœtus, that the uterus was not then physiologically prepared for the work, and that the injuries resulting therefrom might prove fatal; and besides, her already deeply lacerated cervix would be an added element of danger. I also reminded her that the child was a living being, even showed her a papier-maché preparation representing the fourth month; that at that time the fœtus was a perfectly formed child. She looked at it, tears came into her eyes; she said, "Is it so formed?" But she soon controlled her feelings, adding, "I do not believe God has anything to do with it, I shall get clear of it." Can anyone realize the stony hardness of her heart? I reminded her that this child might one day be a blessing to her, probably was given to comfort her in some trying period of life. Again I asked her, "What right had she to interfere with its existence." Then I told her plainly and positively that I would not, for all she had, and twice the mines of Golconda, help in so foul a deed. I heard nothing more from this woman until the fifth of the next May, when I was called to attend to her confinement. After the confinement she was able to be up in nine days. A month after I repaired successfully the old laceration of the cervix.

I hold that a woman who can understandingly contemplate such work is in no way to be trusted. This patient left without paying me for the examination, or the two hours' talk by which the child's life was saved, and probably her own; nor has she since paid for my attending her in confinement, or for the surgical operation or the subsequent medical attention. Also the two physicians who assisted me in the operation have received no financial pay for their work; we have only the consciousness of right doing.

The child was a little girl, and many times have I seen this little fairy playing in the street; but will anyone tell me that her young soul was not tarnished by such desires on the part of the mother.

Many beautiful little children are now walking the streets that I have saved—have prevented their mothers from destroying them. These mothers came to me with the unholy purpose and most wicked request. To all alike I have endeavored to show them their error and point them to the right course.

A good woman, the mother of many children, a lady of considerable wealth, and who for years had been a patient of mine, and consequently would have been supposed to have known better; yet this woman joined with her daughter-in law to destroy the latter's unborn child. She coldly informed me that she was going to have it done! I expressed my condemnation in the most unmeasured terms, telling her that it was not only a monstrous crime, but would be a great wrong to the daughter. I said much, and presented many considerations, but strange, this mother was firm and decided; said her son had enough children, and that he had to get along in life. The parties went to a neighboring city to have the crime committed, by whom I do not know. I knew that the time was fixed. I made one more effort and wrote the following letter to the mother: "May 26, 1880. I cannot let this day pass without giving you another warning. I have reminded your daughter of the great danger, that if there is one death in a hundred she may be that one. I have urged her to desist, now I appeal to you. A child that is three months old has as much right to live as one who is nine months old."

This letter was carried by my faithful coachman, and delivered in person. The operator who was engaged to do the atrocious work, I suppose, dared not proceed; at least the child was saved, and possibly, thereby, the woman's life also.

In 1882 I was sent for to see a Mrs. M——. She was the mother of a large family of children, and was then in the fourth month of her ninth pregnancy. The uterus was in extreme retroversion, there was a deep transverse laceration of the cervix, and the perineum gone. I restored the uterus to position, and put in place a Thomas Cutter's pessary, which made traction from without and held the organ securely. The patient showed very much improved conditions, was comfortable, and in every respect progressing well, when her sister, who prays and talks in meeting, called to see her, and insisted that the child be got rid of, that the patient should not be allowed to suffer, saying that her sister had already more children than she could take care of. Thus this sanctified woman wanted to destroy the four months' old child, and was urging me, the physician in attendance, to do the deed. I reminded her that the patient was doing well, that she would suffer vastly more if such procedures were adopted, that in themselves they were full of peril. Yet this eminently pious lady still insisted. It was now my turn to give "a Bible Reading." I only reminded her of the sixth commandment, and then left, with the authoritative command that the patient should in no way be disturbed. Four and a half months after, I attended the woman in confinement. She was delivered of a fine, healthy boy, without any unpleasant symptoms. A few months later, I repaired for this woman the lacerated cervix and perineum. She did well in every respect.

Mrs. B——. The patient was a happy wife and mother. I had attended her in several confinements; her luxurious table was surrounded by many "olive vines." She removed to a neighboring town; she sent for me. I found the patient very much emaciated, and the abdomen enormously enlarged. After a most careful examination I pronounced her in the fifth month of pregnancy, with probable dropsy of the amniotic coat. She was grieved to hear of the pregnancy, and said: "I must get clear of this; I must." I showed her a more excellent way. She heeded my counsel, and, four months after, I attended her in confinement. Amid the multiplicity of water there was the little, silken-haired baby. Subsequently this woman was again pregnant, and this time was threatened with a miscarriage; she sent for me; I took measures to prevent it. She said: "Let it pass, let it pass, I have too many children." The child was saved. He is now the pride of the family.

Many a woman who asks that abortion may be produced would be very far from it if they understood what it signified, or had an idea of the enormity of the crime. A kindly hearted woman came to see me one day, she was in distress, she had been unfortunate. "The time," said I, "for you to have thought of these things was before the first wrong step, the only way now for you is the path of rectitude." I asked her if she would deliberately destroy a human being. "Why," said she, "it is not a living being until it moves." "It moves a long time before you perceive the motion, and it is a living being from the first." She seemed almost frightened at the contemplated act, and left saying on no account would she allow anyone to commit the deed.

In 1888 or 1889 a patient came to consult me for continued ill health that had existed since early menstrual life. She had been married a number of years and had no children. I found the cervix anteflexed, uterus re-

troverted, and the ovaries enlarged, prolapsed, and congested. After some weeks' treatment her improvement in all these respects was marked. The pain in the pelvis very much diminished, the ovaries were reduced in size, and were less sensitive and sore. A few days before she was to return to her home in another city, to make drainage more complete for the uterus and the adnexæ, I again dilated the cervix, remarking to the patient that "there might possibly be a chance of her becoming pregnant." At the expiration of some months the patient returned for further treatment. I found she was pregnant, I informed her of the same, supposing it would be a cause of great joy and congratulation. On the contrary, she was grieved and depressed; and, to use her language, asked if "she could not be relieved." Even her husband called and ventured to introduce the subject. I told him of the perils of such procedures, that I considered his wife extremely and unexpectedly fortunate, and believed it was her last chance; that certainly she ought to consider it her's and her husband's greatest happiness.

The wife continued to take sad views of the situation, and after their return home she wrote: "Oh, my dear doctor, if it only had not happened. I cannot be comforted with your idea that it is a blessing. Will you please tell me of something that will take away this sickness of the stomach, for I feel that I would rather die than live like this."

Again she wrote: "When I came home the first time I had not felt so well and happy in all the years of my married life. Everyone remarked how well I looked—but oh, this trouble—oh, dear doctor, please help me out of it—I cannot have it so, and if you will not I will do something. I cannot let it go on. I was so nervous at night that I felt I could kill myself. Please give me something or do something, for it nearly makes me wild. I want to be free, that I may get well and take my comfort." Poor misguided woman!

I wrote the husband at length, repeating what I had said in a previous conversation. A later letter from the wife says: "I have given up all hope of this passing away, for it must be three months. Oh dear! I have so longed for it, I know that I shall never live through it, and sometimes when I think of it, I feel like killing myself—am no more reconciled. I was in hopes to write you I was all right once more, but no such pleasure is mine. Good-by, good by, with love and thanks for making me as strong and well as I am, even if you did get me in more trouble than I was before."

I warned the woman again and again, yet she found someone, in her far-off home, who would undertake it. "September 30, 1890. My dear Doctor: I have been very sick. I was taken unwell, and it terminated in a hemorrhage. The physician used cotton, sponges, etc. If I attempt to walk across the room, the pains come. What I so longed for and prayed for has happened, and now I do regret it, for it was a little boy, and I suffered as much as if I had gone through it all, and nothing to show for it. It is five weeks, to a day, since I was taken sick, and here I am, not out of my room, and have my nurse with me yet, and am now beginning to think I shall always have to keep her. I am again flowing, and the last two days it has been very bad. The doctor left me some medicine. I am so discouraged that I cry most of the time. I am so sore that I can hardly move, and have such a heavy feeling. Write me as soon as you can spare a few minutes, and tell me how I can get well, instead of being so sick and miserable."

This poor young woman never will be as well as she otherwise would have been. If she had let the pregnancy continue, she would have had a normal parturition, and been better physically and mentally than she had been in years; and I believe her hysterical nervousness, from the congestion of the ovaries, would have gradually disappeared. She is now a sick woman, and it will no doubt take a long time to repair the injury she has done herself; and how can she ever rest under the thought of having destroyed her own child, probably the last that will ever come and ask for her loving embrace. This poor woman could not comprehend the enormity and danger of her work.

Some know well all they do, the full significance of their crime, and their doubly stained souls are filled with deception. April 20, 1890, a woman called to see me, with a man whom she said was her husband, requesting to consult me in my private office. She gave her name, and said, "she had been married twelve years, had one child ten years old, and was now two months pregnant, and wanted to be relieved." I examined her case, I told her she was not pregnant, and did not believe she could have a child in her present condition. She repeatedly said, "Pass the sound, pass the sound." Under her supposed condition this seemed so brutal I thought that a woman who could so speak was "fit for treason, stratagems and crimes," *and conspiracies!* I dismissed her from the office, and in a few minutes went into the parlor to speak to the "supposed husband." Both had disappeared! I sent a letter to the fictitious name, and to the probably fictitious address, emphasizing all I had said, and adding that the apparently innocent expression, "Pass the sound," might be fraught with tremendous evil; and, to my mind, in her supposed condition, was cruel and wicked.

One Saturday morning, in September, 1890, my door-bell rang; I was called to the office; there stood a young married woman. She related her clumsy story. Without ceremony I should have dismissed her, but wanted to give her a word of warning, and show her the exceeding sinfulness of her proposed course. I called a friend from the parlor, a lady of rare intelligence, who kindly added to and emphasized all that I had said. This young, ignorant, coarse woman, recovering herself, said, "It is a commercial transaction, you give me the medicine, I give you the money." She imagined it a fine argument. There she stood with her paltry dollar, her husband probably making $7 or $9 per week. Ten million times the wealth of Europe and Asia would have been a trifle far too small. Turning again to the woman I said, "Absolutely, if a grain of medicine would enable you to carry out your vile purpose, I would not, for unnumbered millions, give it to you."

One Sabbath-day, in September, a girl, some twenty years of age or over, called to see me. A few touches painted the tragic story. She said she wanted her courses brought on. "Do you know what that means?" said I. "It is one way of destroying your child, now two months old. You are sorry for what you have done, and want to hide it; you cannot. The only right way is to have the child, whether you marry the man or not." She left, promising that she would go to no one for the wicked purpose.

A school-girl came in the summer of 1887. She was pregnant, and in distress. She said that she was able to pay for it, and would go where she could have it done. I said, "To you it will be especially dangerous, you have been diseased since early menstrual life." She said, "There were doctors that would do it for money." "Don't let anyone do it. Your only right way is to go through with it. You do not know what may be the consequences of another course." I wrote the same and more in a letter to her mother, requesting the daughter to deliver it. I knew nothing more.

One day a beautiful young girl, aged sixteen, reared in the lap of luxury and wealth, came in a coupé with her affianced and false lover. She had in her hands a large roll of bills, which she held prodigally and wanted to give lavishly. I felt her very presence was contamination. Said I, "You are an only daughter, your mother knows nothing of this, your father does not know where you are." They had given her every luxury, but had not given her the most valuable of all—parental control, instruction, and discipline.

I hold that children should be educated in the right way and taught to do right. If they have coarse natures which prevent them from going in the right path, they

should be made to do right. Eli's only sin was that he did not *make* his sons do right. In unmistakable terms I gave the girl words of warning. Her beautiful face listened kindly to all I said. She went I know not whither.

How many are taken from the home of innocence and purity, scarce conscious of what they are doing; they do not realize the heinousness and great wickedness of this one false easy step. After! Oh, heavens! The pall of darkness comes upon them, they go deeper and deeper.

One young man sent the following letter to Dr. Charles N. D. Jones, when he was House Surgeon in the Brooklyn City Hospital:

"I am in a little trouble, and I want you to help me out, if you can. A young lady friend of mine I am afraid is in the family way. Now, I will not keep it from you, I think I am to blame. It has only been a week, so you can fix her easily, I think. I wrote her to come to you, but if she does not, will you please call and see her? She lives (he here gives the number and street). You send the bill to me, and I will fix it. She has not had her usual monthly sickness, and I am frightened. As soon as you get this, please call and see her. Her name is (he here gives the name in full). Now, please try and get me out of this trouble, and I will be everlastingly indebted to you. It is not convenient for me to come up to the city, else I would go up and bring her to you. Hoping that you will be able to fix her all right, and trusting that you will, of course, keep quiet. Get me out of this trouble. I remain, etc."

The reply:

"City Hospital, Brooklyn, July 31, 1884.

"Mr. ——: Yours of the 29th received. Your friend was here to see me the day before I received your letter. I must answer you as I did her. I would not think of doing the least thing to bring on her courses, and no man in his right mind would presume to ask me to do such a thing. I must positively decline to aid in any such work. Yours, etc.,

"C. N. D. Jones."

This trusting young girl was sent to the office of a young doctor in a public institution, saying: "Send me the bill, and I will fix it." But how will he, the lover, ever fix it with the young girl. That girl's mother trusted him!

The way back condition, as I have before intimated, is that mothers should instruct their daughters, teach them first parental obedience, and then all that relates to their high moral duties and obligations, unfold to them the great principles of life, of their physical being, their organization, and then tell and explain to them the beautiful laws of health. This is necessary for every day welfare. Why should not young ladies study these subjects as well as rocks and stones, stars and flowers? Does she hesitate to examine a flower, acknowledge it a thing of beauty and joy forever? Just as pure is it to examine this greatest of nature's work. Girls are ignorant and uneducated, and thousands are led into evil and every-day violations of the most ordinary laws of health as well as of morality, for want of knowledge, or because they have not been properly trained and instructed.

In 1887, a young girl, scarce eighteen years of age, called to see me; she wanted to know if she was pregnant. I found her in the second month. She told me the sad story, and said with burning tears, "It must be taken away." I could not say to her, "Marry the man!" The one who had so treated this young girl had sacred and legal obligations to another. I could only say to this child, "Go and tell your mother, she is your best friend; but destroy the child, you must not." If one for his wife's honor may shoot down the betrayer, how infinitely much more does he deserve such a fate, who leads astray and blasts irretrievably the young girl.

A sad, broken-hearted woman, lifting her beautiful face to heaven, vowed that she would destroy the wretch, the author of her misery, nor would she nourish or give life to the product of his being. He made her promises of marriage, but left her overwhelmed with anguish. Why will women trust and sacrifice so much?

Another young woman, of more than ordinary intelligence, was in despair and broken hearted. Her child was born in a public institution. As the mother looked upon it as from him who had blighted her hopes, she vowed that she would destroy it. It was necessary to watch her night and day; for, continually and constantly she threatened the child's destruction.

One, in her shame and desperation, drowned her own little helpless one. Ever she saw the little outstretched hands of her own babe pleading for help. The picture never could be effaced. She became wild, her reason dethroned, but where was her betrayer? She was wrecked, but no one suspected him of wrong doing.

"One more unfortunate." The young and beautiful daughter of a goodly man trusted a young student. He went to honor and emolument, she to insanity and death.

Thousands perish thus in misery and desolation. Women are always the greatest sufferers. Nathaniel Hawthorne relates a touching story of human frailty. The young and beautiful Hester Prynne stood on the pillory of public shame; a select number of wise and virtuous persons, all with grim rigidity and cold severity, were on a high platform, to deal with this poor girl, touching the vileness and blackness of her sin. There she stood, under the weight of a thousand unrelenting eyes on this, to her, a scaffold of execution. One of the said righteous judges to condemn the young woman, was the father of her child!

A similar touching incident is related in an ancient volume; and, probably, from it, Hawthorne gets the gem thought of his classical story. Judah, a great man, high in office and high position, heard that his daughter-in-law had played the harlot. His righteous soul was filled with holy horror. "Bring her forth, and let her be burned." The young woman stood before the assembled multitude. "Discern, I pray thee, whose are these, the signet, and bracelets, and staff." Judah acknowledged they were his. Months before he had met this young woman behind the rocks, and this pledge he had given to her!

A story is told of another judge. Again, a lonely and desolate woman stands before an incensed multitude. "Master," said they, "she was taken in the very act." The judge, with words of infinite wisdom, said unto them, "He that is without sin among you, let him first cast a stone at her." "And they that heard it went out one by one, and the judge was left alone, and the woman standing in the midst." Not one of all that vast multitude could cast a stone!

There is another chapter of this medico-moral legal subject that cannot be omitted. Very lately a gentleman, of high respectability and intelligence, called, informing me that his wife was pregnant; but that neither he nor she thought it right to have this child, adding, "that any doctor who wanted a good practice should take care of his families; that this was the physician's duty, and it was done by the best." I replied, "It can be the duty of no one; and no promise of practice would be of the least consideration." The gentleman unwittingly mentioned the name of the physician whom his wife was then consulting, and stated that this physician "had already put something in the womb that had made her flow," at the same time assuring him, her husband, that "all would be right." This gentleman also remarked that "he had sent this physician fifty such cases," then quoted the words of a medical man who had said: "Abortion was not legal, but it was right."

A few months after, it happened that I again saw this young man, and remarked to him, "So your wife lost her child. Do you know how the doctor did it?" Before thinking, he quickly replied, "Yes, I do, I know exactly how he did it." Alas, alas! it was done, and by a physician, and he a member of a County Medical Society!

An article, in the *New York Gynecological Journal*

says:[1] "The specialist in abortion exists. He is no ideal, but an actuality, a real living man, as a professor, ably filling a chair in college, he is perhaps well known. As a specialist in abortion, he is recognized only by a favored few."

An editorial, in the same number of the journal quoted above, says: "Practices, not infrequently carried out nefariously, by reputable physicians. Some hypocritically practise it in secret, while repudiating it in public." This editorial further makes the startling announcement: "It can be no secret to those of us who have been even a few years in active practice, that fœticide, in the early months of gestation, is constantly performed with the flimsiest excuses, by prominent reputable men and women too, in every community," adding: "This has long been a plague spot in the profession."

I cannot agree with the words of the editor, or of his correspondent. I absolutely deny the assertions, though, four times lately, I have heard physicians say, "All do it;" and a member, at the annual meeting of the Tennessee State Medical Society, asserted,[2] "I fear that the profession frequently takes a hand in the nefarious business." This also is untrue. It is not the profession. It is a few unworthy ones in it. In no profession are there men of more exalted morality, nobler aims, and purer integrity than in the medical profession. They do what is right. With large-hearted benevolence, they aim at doing the best for all.

In 1883, I stood in the parlor of a prominent member of the County Medical Society above referred to; the member pointed from his window diagonally opposite to the residence of another prominent member of the same society and said, "That man will do it any time for $50." I did not believe it then, nor do I now. (But how these brethren love!) It is sadder to know that one member of this same County Medical Society, and one who held a position in the Health Department, was sentenced for this offence; and, as I am informed, others in the same society have been under suspicion.

The writer of the article in the *New York Gynecological Journal*, further says: "We opine that the world would be better if abortion were done oftener."

What doctrine is this to teach in a medical journal! Certainly, the profession does not stand by such teaching. Good men, everywhere, raise their voice against the evil.[3] As far back as 1857, at the annual meeting of the American Medical Association, a committee[4] was appointed to investigate the subject, with a view, if possible, to the suppression of the growing evil; which committee, at the annual meeting, 1859,[5] made a report saying: "As a profession, we are unanimous in our condemnation of the crime; and, as a committee, would advise this body, representing, as it does, the physicians of the land, publicly to express its abhorrence of the unnatural and now rapidly increasing crime of abortion—the wanton and murderous destruction of the child." The Association then unanimously passed the following resolution: Resolved, "In view of the prevalence and increasing frequency of the crime, publicly to enter an earnest and solemn protest against such unwarrantable destruction of life."

But farther back than this, Hippocrates, the father of medicine, in the Hippocratic oath, pledged each of his pupils—and to which every physician must swear—never to be guilty of unnecessarily inducing miscarriage.

In May, 1871, soon after the startling disclosures in connection with the professional abortionists, Wolff and Lookup, the New York Academy of Medicine passed a resolution in reference to the "wide-spread crime." Again, September 21st of the same year, the Academy adopted a set of resolutions, pledging, "All its influence, its efforts in support of any legislative or other measures, which our law officers may propose, as offering a reasonable provision of mitigating, if not removing, the perpetration of criminal abortion, which is upon our country." The Medical Society of Berks County, Pa., passed similar resolutions. The New York Medico-Legal Society appointed a committee[1] whose report was made and unanimously adopted, at the Society meeting held on December 14, 1871, at the College of Physicians and Surgeons, of which the following is an extract: "As the proper name for the intentional destruction of the fœtus is murder, it is hoped that the time will arrive for its punishment as such."

At the meeting of the Crawford Medical Society,[2] on July 5th, the following resolution was passed: "Whereas, the practice of criminal abortion is steadily increasing, and in numerous cases which prove fatal—be it resolved that we petition the Legislature of this State, at the coming session, to enact a law by which the dying declarations of a person, who may die from the effects of a criminal abortion, shall be received as evidence in trial of anyone indicted for such offence." Copies were sent to various medical societies for consideration.

The *Journal of the American Medical Association*, Chicago,[3] calls it the highest crime—from some standpoints, at least—of which humanity is capable, and whose prevalence exceeds the highest estimates." He says, in another number:[4] "The obligation rests upon the medical profession to propose a method for checking the fearful progress of this evil."

The *Boston Medical and Surgical Journal*:[5] "A crime in itself one of the foulest, and against which, in times past, the severest penalties have been attached, and which three hundred years ago subjected those convicted of its committal to all the penalties inflicted on murderers." It adds: "With regard to the proposed remedies for this evil, we confess we have little confidence in mere legislative enactments. It is rather to the medical profession, and those more immediately connected with the morals of the community, that we are chiefly to look for the true remedy. The physician may do much by warning his patients against the dangers and guilt of this awful crime, involving, as it does, the guilt of murder and a cold indifference to the most sacred privileges with which woman is endowed."

An editorial in the *Medical News*[6] says: "The *News* has contended that it is the duty of medical men to instruct the lay world, through the lay journal, concerning hygiene and medical truth."

The report of the committee of the American Medical Association[7] further said: "If to want of knowledge, on a medical point, the slaughter of countless children, now steadily perpetrated in our midst, is to be attributed, it is our duty, as physicians and as good and true men, both publicly and privately, and by every means in our power, to enlighten this ignorance."

The *Australian Medical Journal* said: "We need a medical bill for the colony. Within a week four women in the prime of life have been sacrificed."

The late Professor Hodge, of Philadelphia, in his introductory lecture, quotes the ruling of Judge King, of Philadelphia: "Every act of procuring abortion is murder, whether the person perpetrating such act intended to kill the woman or merely feloniously to destroy the

[2] Transactions, fifty-fourth annual meeting, State of Tennessee Medical Society, p. 176.

[3] I am glad to record also that this young and vigorous journal condemns it; it says: "We heartily reprobate the article by Dr. Harris, not merely because we are opposed on principle to the practice which he advocates, but equally because his advocacy of them is illogical, and founded upon arguments of expediency which appeal to self-interest of the lower and more dangerous kind" (p. 846).

[4] This committee consisted of Dr. H. K. Storer, of Massachusetts; L. W. Blatchford, of New York; H. I. Hodge, of Pennsylvania; Barton, of South Carolina; G. A. Pope, of Missouri; A. Lopez, of Alabama; W. A. Brisbane, of Wisconsin; A. J. Semmes, of District of Columbia.

fruit of the womb." Dr. Hoag[1] says: "All believe the practice to be sinful as well as criminal." H. R. Storer says, in his essay: "The offence is one of the deepest guilt, a crime second to none." J. B. W. Newlin[2] says: "To correct the evil, recommends that the profession should teach the public the facts of embryology, in so far as they relate to the enormity of this crime; that they should thoroughly instruct our lawmakers, so that laws may be formulated which will let no guilty one escape."

The writer in the *New York Gynecological Journal* above quoted, further remarks: "Poor women are to suffer and to sacrifice everything at the shrine of maternity, as if it were for this alone they were made." I reply, maternity is woman's highest mission, and should be her greatest pride. While a woman may possibly accomplish, in other directions, all that is high, noble, and good, yet everything should bow to maternity. This is the shrine to which she brings her noblest offerings. Is she educated, has she physical health, and physical perfection? Are her mind, heart, and soul cultured and highly endowed? It is that she may give birth to more perfect and more beautiful children. This is the end, and should be her highest aim. This also should be the object of a mother's earliest solicitude and training for her daughter. To the shrine of maternity all should be dedicated. As I said in an article:[3] "She is a magnificent woman who can give birth to a large family of children and still retain her health."

The writer in the *New York Gynecological Journal* continues: "What sense is there in allowing a woman with diabetes, albuminuria, and the grave forms of disease, to run the gauntlet of pregnancy and labor? At once empty the uterus." This, when life is endangered, may be judicious; but, in general, if one's individual judgment may decide whether it is best for a child in utero to live, may not the same individual judgment decide whether it is expedient for a boy or girl of five or ten years of age to live. If, in one's judgment, a human being in utero may be destroyed, with equal right may we not destroy a human being at any age of existence? May we not, at any time, decide whether anyone's life is useful or to the advantage of him or herself and to the community? Is not this a most dangerous doctrine? Could a more cruel despotism exist? A physician has no more right to destroy a human fœtus, because he imagines it, in future years, may be sickly, than he has a right to destroy the delicate baby, because it possibly may have before it years of invalidism.

The writer of the same article next gives explicit directions as to how abortion shall be produced. He says: ". . . ," etc. He continues: "Snare No. 1 is passed into the uterus; sweep the staff around the globe of the ovum. Pull gently with forceps, until the mass is either extracted entire or cut in twain. In the latter event, repeat the procedure until it" (the baby!) "is chopped into fragments of easy extraction!" Hail horrors! lay on, Macduff. One almost shivers in reading these descriptions, and for this horrible work the writer holds out the inducement of "handsome returns and fat fees for special services."

I maintain that all this work is murderous, unprofessional, and degrading to the high office of a physician. A physician stands as a preserver of life, and should be the embodiment of honor and high morality.

November, 1893.

The Consumption of Absinthe.—According to some statistics recently issued by the French Government, the consumption of absinthe in France has risen from 57,000 hectolitres (1,254,570 gallons) in 1885, to 126,000 hectolitres (2,773,260 gallons) in 1892. The increase in the consumption of other alcoholic beverages during this period has been nearly in the same proportion.

Progress of Medical Science.

Acute Vertebral Osteomyelitis.—Dr. Morian relates two cases of this rare disease. An important complication consists in the spread of the inflammation and suppuration into the spinal canal. From the front the pus could not so easily penetrate into the canal owing to the ligament, but behind there is a space between the dura and the arches filled with a loose and vascular tissue to which the suppuration has ready access. The membranes and the cord itself may also become involved. In one case pus escaped from the situation named above when the spinous process and arch were removed, and in the second case the abscess extended from the third cervical to the twelfth dorsal, and from here again down to the third lumbar vertebra. The pleura or peritoneum may also become involved. The suppuration is more likely to remain localized behind the peritoneum than behind the pleura. Osteomyelitis of the spongy bones is likely, according to the author's experience, to run a more unfavorable course than when the long bones are affected. As to the symptoms, the onset was rapid, with fever and pain in the part of the vertebral column involved. The column was held rigid. At first the second case resembled epidemic cerebro spinal meningitis; the head was drawn back, the neck and back muscles rigid, and the pupils unequal. Later, however, the pain became more localized, and a swelling appeared. In the acutest cases death may occur before the site of the disease can be localized. Prevertebral suppuration may cause diagnostic difficulties. Acute rheumatism very rarely affects the vertebral column, and then other of its manifestations are present. Acute pneumonia or lumbago might be confounded with it. The prognosis depends on the severity of the toxic symptoms. It is more serious if the dorsal vertebræ are involved, owing to danger of spread to the pleura. The abscess should be opened as soon as possible, and the focus of disease, if it can be got at, scraped away, or better still, as in the case of the arches, removed. The first case occurred in a boy, aged ten. He had pain in the loins, headache, and fever. He kept his back rigid. Some ten days or so later a swelling was found along each side of the lumbar spinous processes. This was incised, and the spinous process of the fourth lumbar vertebra and a part of the arch on either side were removed, pus escaping from outside the dura. A swelling over the foot had also to be incised, and subsequently another one over the humerus. The boy eventually made a good recovery. In the second case of a lad, aged seventeen, a swelling appeared in the region of the eleventh and twelfth vertebræ about seventeen days after the onset. This was incised, and the vertebra found bare. There was some improvement, but the pleuræ became involved, and the patient died. The body of the vertebra showed foci of pus. A communication was traced between the pleural cavities and the disease. The outer surface of the dura was altered. Small abscesses were present in the kidneys. The staphylococcus was cultivated from each case.—*The British Medical Journal.*

Four Children at one Birth, two boys and two girls, all healthy and well developed, is the record of a proud and happy mother in Tennessee.

Mrs. Kadumbini Ganguli was the first native female graduate of the Calcutta University. She passed the L. M. S. examination of the Calcutta Medical College with credit seven years ago, and last year became a licentiate in Medicine and Surgery in England.

Normandy Cattle.—The *American Veterinary Review* recommends the introduction of Normandy cattle (Cotentine the breed is called in Europe) to take the place of the Jerseys which are so prone to tuberculosis. The editor says that in addition to the fact that the breed is claimed to be the finest milking race in the world, it is free from pleuro-pneumonia and tuberculosis.

MEDICAL RECORD:

CAUSES OF DISEASES PECULIAR TO WOMEN.

THE causes of diseases peculiar to the female sex are surprisingly few in number and limited in character. Ignorance and neglect seem to be the most powerful factors in the production of such disorders. A paper in the *International Medical Magazine*, August, 1893, by Dr. Charles P. Noble, states that these causes are about five in round numbers. The first in importance is imperfect development of the sexual organs. Gonorrhœa comes next. The third is septic inflammation following childbirth. The fourth is lacerations due to childbirth. And the fifth may be said to be mechanical and chemical, viz., constipation, erroneous habits of living, and errors in dress.

Imperfect development of the sexual organs as a cause of disease in women is often overlooked. As a rule, when the development of the sexual organs is interfered with, the development of the whole body is also arrested. Almost without exception, such women belong to the class of neurotics. They are especially liable to neuroses, especially chorea, headache, and neuralgia. Puberty is often delayed, and menstruation is always painful. The pain belongs to the type of the so-called ovarian dysmenorrhœa: it begins a day or several days, perhaps a week, before the menstrual flow, and is especially felt in the ovarian region. Uterine dysmenorrhœa, due to lack of development in the uterus (especially of the cervix), is frequently present. The pain is paroxysmal, and less marked when the flow has become fully established. Too much school work and too frequent examinations impair the tone of the nervous system, stimulate emotion, interfere with digestion and sleep. Anæmia and depraved nutrition follow, and these in turn aggravate the neurotic state. When such girls arrive at puberty there is not enough vital force left over for the proper development of the sexual organs. The most remarkable cases of this arrest of development are to be found among the very poor, among girls who have not been forced at school, and who in some instances have never been to school at all. The cause of arrest of sexual development among them is hard work undertaken too early and steadily, as in mills and factories. Absence of fresh air, outdoor exercise, and this excess of work, do for the very poor just what lack of fresh air, outdoor exercise, and too much study and excitement, do for the rich. Menstruation among these girls is tardily established, never perfectly performed, and may cease or become irregular between the twentieth and thirtieth year. One common cause of this arrest of development in the female sexual organs the author has overlooked, and that is infectious disease during childhood. Scarlet fever, measles, mumps, diphtheria, etc., set up inflammatory processes here that result often in permanent damage to the tissues. There is not only arrest of development in these organs, but there is also destruction of their substance proper, due to the various poisons of infectious disease. Neurotic girls need lighter tasks and more fresh air and sunshine than their stronger sisters, more rest, and more sleep. Any functional disease should be attended to at once and cured. This will help store up vital force for the exigencies of puberty. When menstruation fails to appear at the accustomed time, special care is necessary, the case being watched carefully till menstruation is fully established. Such a plan as this must of necessity diminish dysmenorrhœa and sterility, and laceration of the cervix and the perineum, and also decrease the cases of chronic ovaritis and ovarian cystomata.

Gonorrhœa, one of the most prolific sources of disease in women, is to-day very generally recognized, though a knowledge of its full significance is of recent date. Noeggerath, in 1873, published his paper on "Latent Gonorrhœa in Women," and called attention to its serious ravages. His views met with fierce opposition at the time, but their truth has been established by the work of modern abdominal surgeons. It is now well known that gonorrhœa is one of the chief causes of uterine, tubal, ovarian, and peritoneal inflammation. The exact percentage is not yet determined. Cities containing great numbers of the poor and the vicious, and of the rich and immoral, give a higher percentage than rural communities having a more decent population.

Septic vaginitis, endometritis, and metritis, are well known forms of puerperal inflammation. They frequently persist and require treatment after the puerperal period. Aside from the more rapidly fatal cases, the most serious result of infection during labor is the spread of the septic inflammation to the uterine appendages, giving rise to salpingitis, ovaritis, and peritonitis. Sometimes there is perfect recovery. More often the result is chronic inflammation, with formation of adhesions to the neighboring structures, or the collection of fluid, serum, blood, or pus, in the tubes or in the ovaries. How far this is due to puerperal septic inflammation, and how far to latent gonorrhœa, is a mooted point. A much less frequent result of puerperal infection is acute inflammation or abscess of the broad ligaments. Phlebitis and its associated condition, *phlegmasia alba dolens*, are other abnormal manifestations due to puerperal septic infection. Gonorrhœa and puerperal sepsis together cause fully ninety five per cent. of all cases of tubo ovarian inflammation.

Lacerations due to childbirth are also followed by conditions disastrous to health. Those of the pelvic floor are even more important than lacerations of the cervix uteri, since cystocele, rectocele, and prolapsus uteri are directly due to them. Constipation is a bad habit common to women, and one that predisposes to the development of hemorrhoids, and to uterine and ovarian congestion, to retroversion of the uterus and prolapse of the ovaries. The full rectum can displace the cervix forward,

and the straining at stool, especially if the bladder be full, can topple the uterus over backward. Relaxation and loss of tone of the pelvic tissues due to congestion, also predispose to retroversion of the uterus and to prolapse of the ovaries. Constipation aggravates the symptoms of every pelvic disease, partly by pelvic congestion and partly by general deterioration of health, due to fecal absorption and contamination of the blood, and by loss of appetite and disordered digestion. Indolence, luxury, or the strained and monotonous life of the poor, induce pelvic disease. Tight corsets, tight bands about the waist, heavy clothes, heavy skirts, tend to displace the abdominal viscera downward. As rational dress is perfectly possible at present, without sacrifice of taste or beauty, these evils are no longer necessities.

The remedy for diseases peculiar to women, since they are so largely preventable, is to be found in applied knowledge. Growing girls, especially about the time of puberty, require care that will secure for them a normal development of the sexual organs. Gonorrhœa should be more vigorously treated than it is, the patient kept under observation until all abnormal discharges are arrested, and proper instruction given concerning abstinence in the matter of sexual intercourse. Laceration of the cervix and perineum are to be repaired early. Every effort should be made to prevent the spread of infectious disease. The evil effects of constipation, improper dress, and erroneous habits of living, require constant and careful explanation. This is pre-eminently the duty of the family physician, who is brought in contact with abnormal conditions in women before they come under the specialist's direct and exclusive observation.

THE PART OF THE BILE AND THE BRÜNNERIAN GLANDS IN DIGESTION.

A VIEW which many persons take of their indigestion is that they have "bile on their stomachs;" and they corroborate this by speaking of the bitter taste in the mouth and of various other evidences of a so called "biliousness." Now physiologists have generally been disinclined to believe that bile often gets in the stomach, since it is poured out into the intestine some distance below the pylorus and since peristalsis always occurs normally in a direction away from the stomach.

Professor Herzen, however, in his observations on a man with a gastric fistula, asserts that bile is a very constant ingredient of the gastric juice or, rather, of the chyme (*La digestion stomachale*, p. 78). In 107 out of 142 tests, bile was found in greater or less quantities. This view is supported by the experiments of M. Ch. Contejean, who in a large number of tests upon himself —a healthy man—found bile in the chyme. It is known that bile in any amount, however, retards and may even stop altogether gastric digestion. It is stated that from 30 to 50 drops will stop digestive processes in 3 c.c. of gastric juice. The theory has been put forth by Schiploff that one function of the glands of Brünner is to antagonize this dyspeptic action of the bile.

Dr. J. Belkowski, in the *Revue Médicale de la Suisse Romande*, has made an elaborate series of experiments in order to determine just what function the bile does play in gastric digestion and what the glands of Brünner have to do in the same process.

Dr. Belkowski agrees with the other observers that bile is frequently present in the chyme. He finds that beef's bile is particularly injurious to digestion, much more so than that of carnivorous animals.

He finds further that the secretion of the Brünnerian glands does not have any digestive power when the acidity of the medium is over one per cent. and that the part which it plays in gastric digestion is practically of no importance. The pyloric secretion has an almost equally slight value. Finally he finds that neither of these secretions has any part in neutralizing the bile, and that gastric digestion can and does go on very well despite the presence of bile. Hence a "little bile on the stomach" is more or less normal and does no harm.

The duodenal glands in man are few and probably rudimentary organs, though well developed in the sheep. Even the pyloric end of the stomach may come to be regarded as only vestigial—like the appendix.

THE REFORMATORY INVESTIGATION.

IT is gratifying to observe that the State Reformatory at Elmira is at last being subjected to a really judicial investigation. The verdict rendered against this most famous of penal institutions a few months ago, after an alleged investigation prompted by a vicious newspaper attack, was a surprise and shock to every one familiar with the methods of the institution and its marvellous results in the reformation of youthful delinquents. The present investigation is apparently being conducted in a way to get at the actual facts. Thus far the results are reassuring to those who have looked to Elmira as the most successful reformatory in the world, and to the movement inaugurated in this country by Superintendent Brockway as the one reasonable method of turning back the tide of criminality that is rising so rapidly in most civilized countries.

No brief account could possibly give a comprehensive idea of the work done at Elmira. It is a school whose pupils are criminals from the lowest walks of life, illiterate, vicious, seemingly irreclaimable, and whose graduates are men changed in their entire mental and moral attitude—educated, developed, regenerated. The matriculant is a criminal at war with society; the graduate a skilled tradesman ready to go out and earn an honest living in the world. Of the several thousands treated at Elmira, more than eighty per cent. have gone out thus regenerated, and are now living useful lives. This work has made Mr. Brockway famous the world over. The United States Bureau of Education in a recent report says of him that he is "justly recognized in Europe, as well as in America [note the sequence] as the most successful in the actual reformation of the criminal." For the direct practical elevation of the ethical level of our race, Mr. Brockway has perhaps done as much as any other single individual in the world.

But it chances that one part of the admirable system by which Mr. Brockway has achieved such marvellous results includes the application of corporal punishment to wilful misdemeanants, as a last resort. There was never anything secret about this. Such punishment was always administered by the Superintendent in person, after numerous charges had been preferred and proven, and after the misdemeanant had been repeatedly warned and ad-

monished by the Superintendent. A record of the entire case was always kept in the books of the institution, including not only the fact of punishment, but the exact number of blows administered. The published annual reports of the institution described this portion of the reformative treatment, and it was perfectly understood and generally approved by all persons familiar with the work of the Reformatory. But about a year ago a sensational newspaper in New York made the startling discovery of the existence of this method of treatment, and assailed the institution, with the ultimate result of bringing on the investigation already referred to, of which the present investigation is the sequel.

At the beginning of the present investigation the "terrible weapon" with which the spankings were administered was produced. It proved to be a strap twenty-two inches long, three inches wide, and three-sixteenths of an inch thick, weighing, handle included, sixteen ounces—an instrument, one would suppose, admirably adapted to produce a corrective tingling of the cuticle, but utterly incapable of producing the lasting injuries that were alleged to have resulted from its application. These injuries, damaged spines, impaired vision, and what not are rapidly disappearing when subjected to critical examination in the concrete by expert physicians called by the investigating commission, or by the medical member of the commission, Dr. Austin Flint. It is being shown that the inmates who furnished the adverse testimony before are largely malingerers and incorrigibles. One of them is on record in the book of the Reformatory as having committed about five hundred misdemeanors and breaches of discipline, from attempted murder down, during the two years of his stay in the institution. The marvellously exact and explicit records of the institution—in themselves testimony to the great executive ability of Mr. Brockway—when consulted in full and not merely in garbled extracts, have gone a long way toward clearing up the charges made against the Reformatory management. Admissions made by witnesses called for the prosecution have also strengthened the case of the defence. Already the hope is justified that the researches of the investigating commission will lead to a report fully restoring the Reformatory to its place in the public confidence.

PATENT MEDICINES AND THE TEXAS DOCTORS.

THERE are troublous times in Texas again; but the clouds are clearing, and the Lone Star is beginning to filter its pellucid beams anew over a distempered world. It all began from a combination unfortunately made between the *Austin Statesman* and the State Medical Society. The *Statesman* (who does not seem to have quite grown up) published the remarkable assertion that at a meeting of the Society one of the doctors spoke anent patent medicines as follows:

"No doctor who has any consideration for his calling will prescribe a patent medicine compound for a patient. If he is a doctor at all he will write a prescription containing the same ingredients. By this means the druggist is enabled to make his percentage on the prescription and the doctor gets a rebate. Now, if the doctor prescribes a patent medicine, the druggist only gets a small margin of profit, and the doctor gets nothing at all. So, in consideration of this fact, if for no other, a doctor should never prescribe a patent medicine."

Naturally such an avowal as this led to strong denunciations by the editor, of the medical men of Texas and everywhere else, with incidental criticisms of druggists and their business ways. Slander loves a shining mark; but when it strikes the Texas doctors, the mark not only shines, but corruscates, with a blinding brilliancy that wilts, dries up, and utterly defibrinates the slander. The doctors of Austin got together and passed some resolutions, which we publish in full:

"*Whereas*, There recently appeared in the local editorial or reportorial columns of the *Statesman* an article headed, 'The Reason Why Doctors Object to Patent Medicines, as Explained by One of Them,' in which article it is asserted that the writer had heard a delegate on the floor of the recent Medical Convention in this city state in substance, 'That, by writing a prescription for the same ingredients of which a patent medicine is composed, the druggist makes a larger profit and gives the doctor a rebate;' and, further, that he, the said writer, in a conversation with an Austin druggist, was informed by said druggist that 'it is a common practice for doctors to prescribe a small quantity of a patent medicine and have it put up as a prescription, the druggist charging a much larger price for this part of the bottle thus dispensed than the whole bottle would be sold for; and by that means he made a larger profit, and gave the doctor a rebate.' Or, in other words, that this druggist stated, in effect, that doctors and druggists are in collusion to rob their patrons.

"*Resolved*, That the statement that a delegate on the floor of the recent Medical Convention in this city, at any time during its sessions, made any such statement, is false and libellous upon the medical profession; that members of the Austin profession, who were present and heard all the discussion on the subject of patent medicines, assert positively that no such statement was made by any member or delegate at any time, and that no language was used that could, by any honest interpretation, be so construed.

"*Resolved*, That the statement, by whomsoever made, that any reputable physician in this city is, or has been guilty of any such collusion as is in said article attributed to them, is false and libellous; and we assert that no reputable physician asks, expects, or would receive from his druggist any rebate or percentage on his prescriptions.

"*Resolved*, That the entire article is a misrepresentation of facts, and an unmerited insult to the entire medical fraternity of this city and State.

"J. W. MCLAUGHLIN, M.D., President Texas State Medical Association; T. J. BENNETT, M.D., President Austin District Medical Society; Q. C. SMITH, M.D.; S. E. HUDSON, M.D., President Travis County Medical Society; R. M. SWEARINGEN, M.D.; F. E. DANIEL, M.D., Editor *Texas Medical Journal*; A. N. DENTON, M.D.; E. V. HAMILTON, M.D.; T. J. TYNER, M.D."

This resolution not only sets the Texas doctors all right, but lays down the rules of a correct and advanced ethics as regards doctors, druggists, patent medicines, and rebates. The *Statesman* has been shown to be an erring mortal and no better than a Populist; the profession of Texas has been vindicated, and the cause of morals advanced. After a stir in Texas the air is always clearer.

News of the Week.

The Number of Medical Students at the Paris Faculty of Medicine has been steadily increasing until, from 384 new matriculates in 1885–86, the number has reached 719 in 1893–94. Despite this the size of the teaching corps is not increased, and the students do not have sufficient personal instruction from the faculty. Unless something is done, Paris will soon fall still further behind as a great teaching centre.

Prunus Virginiana as a Heart Tonic.—There is yet another drug which I venture to think may be unknown to some of you. That is the prunus virginiana or American wild cherry. My attention was first called to it some years back by an article in one of the journals by Dr. Clifford Allbutt. I can reiterate all that he says in praise of the drug. It relieves the flagging and distended ventricle of the chronic bronchitic, it stimulates the flapping chambers of the anæmic, and it increases the muscular tone in subjects recovering from fever and other exhausting diseases. It is also given with great advantage in the irritable "convulsive" heart of the overworked man of feeble physique. It is especially useful in dilatation of the right heart, whether as a result of chronic bronchitis or of mitral stenosis. I use it more in private than in hospital practice; and perhaps no drug has brought me so much credit.—Dr. Seymour Taylor, in *The Clinical Journal.*

Discovery of the Bacillus of Acute Rheumatism.—A number of the clinical features of acute articular rheumatism have suggested to the minds of many the probability that it belongs to the ever-growing class of infectious diseases. Its acute onset and febrile and self-limited course, its complications, and the frequent involvement of the joints as a complication of many infectious diseases, are regarded as supporting this theory. The careful investigation of a typical case of the disease by Sahli (*Deutsches Archiv f. klin. Med.*, 1893, p. 451), has added the evidence of the bacteria themselves. Endocarditis, pericarditis, and pleurisy were associated with the joint lesions. There was no suppuration. Bacteriological examination disclosed the presence in all the lesions of a micrococcus, identical morphologically and culturally with the staphylococcus citreus, but of very low virulence when inoculated into animals as compared with it. As there was no ground to suppose a mixed infection in this case, Sahli regards this germ as its exciting cause. He is in doubt whether the germ discovered is a distinct species, or whether it is merely a staphylococcus citreus of degenerate virulence. He is inclined to the latter view because of the frequent association of rheumatism and endocarditis, whose intimate relationship to the pyogenic cocci has been repeatedly shown. A note appended to the report of this case states that in several other cases more recently examined, similar cocci of low virulence have been found.

In connection with this account, which is abstracted by Dr. Ely in the *American Journal of the Medical Sciences*, we may call attention to the statement of Dr. Edward Grün of Putney (*Lancet*, May 6th), that he finds the blood in acute rheumatism "charged with bacteria in the form of minute cocci," which are easily stained by a warm solution of methylene blue. We fear that Dr. Grün is troubled with muscæ volitantes. Dr. Lucatello, of Genoa, has shown at the Italian Medical Congress of 1892, cultures of a micro organism which he obtained from cases of acute rheumatism. The microbe was small, round, and neither pyogenic nor saprogenic. Altogether, the evidence is as yet insufficient to place acute rheumatism among microbic diseases.

Another Plea for a National Bureau of Health.—The *Maryland Medical Journal* says, editorially: "Once more it seems necessary to arouse the profession to the importance of using every effort for the passage of a bill in Congress to form a National Bureau of Health. It is only by united effort and by constant appeal to our representatives in Congress that the end will be attained. Not only medical journals, but the lay press of all parties have made a strong fight for the establishment of this bureau; and in our commerce with other countries which protect themselves by sending us their sick and diseased, it is no more than right that we should defend this fair country against disease and pestilence from without. In addition there are filth diseases, like typhoid fever, which spread and do incalculable harm and which, without respect to state and municipal boundaries, spread from community to community, and it is for the better protection against disease both from within and from without that a bureau of health is needed. The general work of such a bureau is shown in the proposed bill, which has already been printed."

The Idaho State Medical Society will hold its second annual meeting at Boise, on Monday, Tuesday, and Wednesday, September 10, 11, and 12, 1894. The officers of the Society are: Dr. W. W. Watkins, of Moscow, President; Dr. C. L. Sweet, of Boise, Secretary.

Dr. Juan J. Ulloa, of San José, who was the official delegate of the Republic of Costa Rica to the Pan-American Medical Congress in Washington, has been appointed Secretary of the Interior and of Public Improvements by the President of Costa Rica. Dr. Ulloa is a graduate of the Medical Department of the University of New York, and after serving on the house-staff of St. Vincent's Hospital, practised for a time in this city.

The Plague in Hong Kong is still on the increase according to advices brought by the steamer Peru. During the week ending June 14th over seven hundred persons died of the pest. Five British soldiers are among the victims. The native inhabitants are fleeing from the city, and it is feared will spread the disease through the surrounding districts.

Dr. E. C. Seguin, of this city, has been elected a corresponding member of the Académie de Médecine of Paris.

Dr. Ezra M. Hunt died on Sunday last in Metuchen, N. J., aged sixty-four. He was a graduate of Princeton College in the class of '49, and obtained his medical degree from the College of Physicians and Surgeons in this city in 1852. He was surgeon to one of the New Jersey regiments during the war, and had previously lectured for a number of years in the Vermont Medical College. Dr. Hunt was very prominent in health matters in New Jersey, and had been secretary of the State Board of Health from the time of its organization in 1878.

Society Reports.

Congress of American Physicians and Surgeons.

Third Triennial Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from Vol. 45, page 799.)

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Sixteenth Annual Meeting, held in Washington, D. C., May 30, 31, and June 1, 1894.

FIRST DAY, WEDNESDAY, MAY 30TH.

President's Address.—DR. D. BRYSON DELAVAN, of New York, said that the object of his address was to review the history of the Association, study the means by which it had attained success, estimate its present, and finally investigate the methods by which its mission of usefulness for the future might be most surely and successfully accomplished.

The history of the Association was intimately related to that of laryngology, for Manuel Garcia was still living and one of its Honorary Fellows. It was a pity that Horace Green, who had been the actual leader of the world in the study of diseases of the throat, should not have lived to see the Association established. The laryngoscope was said to have been introduced into this country in 1860. By 1878 its use was being taught in twenty different institutions, and the specialty at first opposed by the general profession had gained a respectable position. The American Laryngological Association was formed in 1878. The motives which actuated its founders were eminently philanthropic and ambitious. The society has been completely successful. Its meetings had been held regularly, they had been well attended and the scientific work done had been of a high order, and the discussions have been remarkably valuable. Its fifteen volumes of transactions were a great credit to it. They contained over three hundred and thirty papers. Meanwhile ten years elapsed before the example of the Association was followed. In 1888 the British Laryngological Association was formed by Sir Morell Mackenzie, and later associations have been started in France, Belgium, Italy, and Holland. Local laryngological and rhinological associations have greatly increased in numbers of late years. The first of these was the New York Laryngological Society, founded by Dr. Clinton Wagner in 1873, and since merged into the very successful Laryngological Section of the Academy of Medicine. Successful local societies exist also in London, Berlin, and other centres. The latest ones have been established in Philadelphia, and Buda-Pesth. Wherever such societies and associations have been established, their influence has been elevating and inspiring, as shown in the improved quality and amount of the scientific work done and in the general tendency toward higher planes of professional education and culture. It is satisfactory that this movement should have been started, and at so great a distance in advance, in this country. The knowledge of this, however, should only serve as a spur to greater exertion on our part.

The American Laryngological Association has always held a leading place in the general and journalistic literature of the specialty, the *Archives of Laryngology* having been one of the first special journals ever published. The influence of the Association upon its members has been stimulating and salutary and has resulted in great good to many. The great function of the society in the past has been that of a teacher. Herein lies its greatest hope of usefulness for the future. It is a teacher of teachers, and as such should not confine itself to laryngology alone, but should pay some attention to the study of pedagogy, as it relates to this department. This has always been carefully considered by our Association as it relates to undergraduate instruction. Of late a great advance has been made in medical instruction in the establishment of graduate schools. This movement, together with the great increase in the literature of the subject, has given to laryngology a startling popularity, and the multiplication of the number of practitioners who assume to treat diseases of the throat has been very great and has called loudly for increased and improved facilities for instruction. This want has been met by the graduate school, which, first started in New York, has become a recognized factor in education all over the country. The greatly diversified nature of graduate students as to age, general and special education, makes the problem of their suitable instruction a difficult one. The theory of graduate instruction in this country is a triumphant success. How, then, can we best attain the practical ends demanded by it? The answer to this was first given by Dr. Elsberg, the Association's first president, who was the first and best to enter this field.

The most important factors in the improvement of graduate instruction are: 1. A higher and more general education on the part of the student. 2. A modification of the best undergraduate methods to suit the needs of the older men. 3. More careful selection of instructors. The future of the Association is bright and promising. It has attained success in the past only by the exercise of much labor and careful attention to its best interests. It would be unwise to lower its standards in any way. The dangers which threaten any such institution are—lack of interest on the part of its older members; the multiplication of other societies; and worst of all, the introduction of politics and the desire of self-aggrandizement. We cannot believe that such dangers can threaten us so long as we live up to the principles upon which the society was founded.

A great change has taken place in late years in the matter of special work, and larger numbers of men are engaged in it than ever before. If, in this vast extension of knowledge, our standards are to be lowered, and work not of the worthiest accepted at equal value with the best, the results will be disastrous to the advance of true science. Such a calamity we are unable to foresee. Outside competition will only stimulate to higher attainment and higher skill, while from the vast body of new aspirants must arise men who will penetrate still more deeply into the hidden recesses of nature. With the progress of science in our department the American Laryngological Association is intimately associated and largely responsible. It is to be hoped that it will respond to the demands made upon it.

Nasal Polypus; Its Association with Ethmoiditis and Its Treatment by Resection of the Middle Turbinated Body.—A paper with this title was read by DR. W. E. CASSELBERRY, of Chicago. An analysis of forty cases confirms the view that nasal polypus is but a symptom or concomitant of other nasal maladies, the most frequent being various forms of ethmoiditis. Two previous papers by the author are reviewed, in the first of which he advised a vigorous surgical treatment having for its object first access to and then eradication of the actual seat of attachment, most frequently in the immediate vicinity of the hiatus semilunaris. For eradication of the attachments, upward beneath the middle turbinated body, he has recently substituted for the cautery point, before recommended, a small sharp curette with which the borders of the hiatus and the bulla ethmoidalis are well scraped.

In a supplementary paper in 1891, he advised, as part of the radical treatment, the removal of the antero inferior part of the middle turbinated bone, in order to give freer access to the actual points of development.

Additional experience with this operation has but confirmed its utility and demonstrated its harmlessness. The middle turbinated body, a process of the ethmoid bone, is rarely itself in a healthful condition in these cases, a phase of the subject which is amplified in the present paper. Furthermore, it appears from the cases reported as typifying the various forms of associated ethmoid disease,

that polypus is commonly one of the earliest prominent manifestations of ethmoiditis, and resection of the middle turbinated bone, in addition to its efficacy for the polyps themselves, is regarded as a prophylactic measure against the development of the more serious suppurative type of ethmoiditis and infection of the maxillary, frontal, and sphenoidal sinuses, by facilitating drainage from the ethmoid cells.

A clinical classification of the various conditions which are found associated with and underlying the formation of nasal polypus is deduced from the analysis of forty cases, and a case typifying the characteristics of each group is detailed.

Type I.—*Nasal Polypus with Hypertrophic Rhinitis.*—This is characterized by simple enlargement of the inferior and middle turbinated bodies and without evidence of ethmoiditis other than the suggestiveness of the polyps. Drainage is defective, and the accumulation of mucopurulent secretion in the middle meatus seems to encourage polyp growth. Recovery without recurrence follows removal of the polyps and reduction of the hypertrophied turbinated bodies by the cautery. Only six of the series of forty cases were of this type.

Type II.—*Nasal Polypus with Simple Myxomatous Ethmoiditis.*—This is characterized by great enlargement of the middle turbinated bodies, which have a glistening aspect and a pultaceous touch indicative of œdematous or myxomatous degeneration; pressure in the ethmoid region, productive at times of infra orbital swelling and broadening of the base of the nose.

After resection of a considerable part of the middle turbinated bone the muco periosteum of the parts of the ethmoid bone thus exposed—the borders of the hiatus, bulla ethmoidalis, etc.—is found in a state of myxomatous degeneration and covered by polypoid excrescences, the same extending upward into the ethmoid cells.

Fourteen of the series of forty cases were of this nature, and five of them were subjected to the operation of resection of the middle turbinated bones.

Type III.—*Nasal Polypus with Vaso-Motor Ethmoiditis.*—This is regarded as a variation of Type II., and presents the same evidences of myxomatous degeneration of the muco-periosteum of the ethmoid region. In addition, asthma was a universal symptom, which, to some extent, influenced the grouping together of these particular cases, under the conviction that asthma of this variety is caused by a similar vaso-motor tumefaction of the bronchioles.

The group comprised nine cases, and four of them suffered from hay fever, which further indicated the possession of a fundamental neurotic habit. They were all affected by supersensitiveness to the extent that various irritants, such as dust, coal smoke, fog, aroma from horses, etc., would suffice at any season to excite a form of nasal tumefaction suggestive of vaso dilatation, and in most cases the ethmoid region seemed especially sensitive.

Type IV.—*Nasal Polypus with Suppurative Ethmoiditis.*—This is characterized by a purulent discharge from the ethmoid cells, co-existing frequently with empyema of the maxillary, frontal, and sphenoid sinuses. It is regarded as a sequel to Type II. or Type III., suppuration occurring only after myxomatous tissue has accumulated sufficiently to obliterate the natural drainage channels, which view is substantiated by a case in which suppuration of the frontal sinus occurred in conjunction with obliteration of its outlet. This group comprises six cases, of which five were subjected to resection of the middle turbinated bone on one or both sides, in addition to other measures.

Type V.—*Nasal Polypus with Necrosing Ethmoiditis.*—Dr. Woakes' contention that nasal polypus indicated a chronic inflammation of the ethmoid is in large measure substantiated; but that necrosis or even caries of bone is a "usual" accompaniment is not confirmed, so that it would seem wise to limit the term "necrosing ethmoiditis" to the class of cases in which necrosis or, at least, caries, actually exists. Only five cases were accompanied by unmistakable necrosis of bone.

Concerning the technique of resection of the middle turbinated bone, the author has devised curved serrated scissors with which to cut the bone for a variable distance backward, when the operation, if not complete, can be finished by the snare or sharp forceps. The resection need not be completed at one sitting, but is more often accomplished fragment by fragment, the latter method alone succeeding when the middle turbinated body is greatly enlarged and closely impacted within its space.

Conversely if the middle turbinated body be of normal contour and present no impediment to drainage, to the transmission of light or instruments, there will then be no occasion to interfere with it.

This paper was discussed by Drs. W. H. Daly, of Pittsburg; F. H. Bosworth, of New York; J. H. Bryan, of Washington; J. N. Mackenzie, of Baltimore; F. W. Hinkel, of Buffalo; W. Peyer Porcher, of Charleston; J. C. Mulhall, of St. Louis; Jonathan Wright, of Brooklyn, and C. C. Rice, of New York. These gentlemen all agreed on the main features of their remarks. Overzealous surgery in the nose should be avoided. One case of severe hemorrhage has resulted. In one instance, immediately after removal of the turbinated, severe parietal pain was felt in the head. The patient became demented and died of cerebral abscesses. The heart could not be examined at the autopsy and it is possible that the brain lesions in this case came from a cardiac embolus, though the patient had always been in the best of health previously. Acute cases of ethmoidal trouble will often subside under local antiphlogistic measures; but in the chronic cases it is useless to expect a cure without radical operative procedure.

Papillary Hypertrophy of the Nasal Mucous Membrane.—Dr. Jonathan Wright, of Brooklyn, N. Y., presented a paper entitled "Papillary Hypertrophy of the Nasal Mucous Membrane Compared with a True Papilloma." The writer stated that there was much confusion in the literature of rhinology, from the loose use of the term papilloma as applied to intranasal excrescences. Hopmann has described a pathological formation, which the Germans speak of as papilloma, but it is not true papilloma at all. Such growths in the nose are rare.

Dr. Wright exhibited drawings illustrating the difference between the two conditions named in the title of his paper. The nasal growth was removed from the middle of the inferior turbinated bone and the true papilloma from the uvula. The latter consisted of a thick stem with irregular sprouts,—some simply conical, springing directly from the central stem, but the larger number again divided into stems and sprouts, the whole looking like a budding tuberous vegetable. A drawing of the nasal growth showed a symmetrically rounded mass, divided by cross lines into more or less regular portions resembling the "mulberry" hypertrophy, so frequently seen on the posterior ends of the inferior turbinated bones. The mass was sessile, but movable, and removed by a cold snare. Although the operation was prolonged over nearly an hour, severe hemorrhage resulted three hours later. As contrasted with the true papilloma, almost any fold of the nasal specimen communicated with the central mass, without any appearance of a "budding" process. The line of surface epithelium was not especially thickened or irregular. The papilloma was without glands, had only small capillaries, and a slight branching framework of connective tissue. The latter was covered everywhere by a large number of regularly situated layers of flat, epithelial cells. The papillary hypertrophy consisted of all the constituent parts of the mucous membrane of the inferior turbinated body. The dilatation of the venous sinuses was especially marked. Glands were present, but scanty. The fibro-connective tissue was greatly increased. This, at the periphery, was divided into regular processes covered by epithelium, and separated from each other by depressions giving a nodular

surface. These growths are papillary hypertrophies of the erectile bodies of the inferior turbinated bones. These enlargements result from a continuous and exaggarated contraction and dilatation of the sinuses in a stroma deprived by chronic inflammation of much of its elastic and muscular structure.

Metallic Electrodes in Nasal Disease.—Dr. C. C. Rice, of New York, next read a paper entitled "The Use of Metallic Electrodes in Nasal and Post-Nasal Disease." His plan of treatment is to make the positive electrode of the circuit of some such substance as copper. When the current passes, the metal is dissolved, and a new metallic salt, the oxychloride of copper, is formed and carried through the tissues by kataphoresis. Allusion was made to the experiments of Gautier, Morton, Cleaves, and others along this line. There was no proof that the action of the salt was germicidal. It was claimed that the new salt was actually carried into the tissues, that it was in this way more efficient than a solution of the substance applied to the surface, and that the pathological foci, being beneath the surface, were thus more effectually reached. Part of the advantage was undoubtedly derived from the current itself and from its own electrolytic action upon the tissues. He had found the treatment especially satisfactory in various forms of nasal disease where, succeeding the removal of all offending material, there was a continuous hypersecretion. Enlarged turbinates could be punctured with a copper needle, the negative electrode being a flat sponge on the nape of the neck. Succeeding the current was a temporary coryza, which usually disappeared in twenty-four hours. He had found the copper needle preferable to the cautery in epistaxis from eroded spots on the nasal septum. Out of twenty cases of these various ailments he had cured six, and benefited fully three quarters of the remainder. Paper discussed by Drs. Wright, A. W. de Roaldes, of New Orleans, J. O. Roe, of Rochester, Daly and Casselberry. All these gentlemen were unanimous in doubting the accuracy of the various milleampère metres which are necessarily used in the foregoing electrical procedure, and doubt was also expressed as to the distinct effect of the metallic salts as apart from the general stimulating one of the current itself.

ASSOCIATION OF AMERICAN PHYSICIANS.

Ninth Annual Meeting, held in Washington, D. C., May 29, 30, 31, and June 1, 1894.

Second Day, Wednesday, May 30th.

Modification, Temporary and Permanent, of the Physiological Characters of Bacteria in Mixed Cultures.—Dr. Theobald Smith, of Washington, D. C., read a paper with this title. The variability of species of bacteria is a most important subject. The changes in virility by passing through animals, and by heat or chemical agents, are well known. The objects of these studies are to determine the modification of bacteria when grown in mixed cultures. In 1890 the accidental association of *proteus vulgaris* with a pathogenic bacillus (*B. choleræ suis*) in an agar culture produced, within a few months, a very marked reduction of the pathogenic powers of the latter. Repeated trials with mixed cultures confirmed this observation. A return of the original virulence of the pathogenic species was noted after it had been cultivated by itself; but this return was preceded by a prolonged period of attenuation, lasting in one instance about nine months.

These results suggest the possible modification of pathogenic and aprophytic species in the soil by similar agencies. They also throw some light on the extent of the mutually destructive action of different species accidentally vegetating together. Dr. Smith detailed at length his experiments. He grew the bacilli of hog cholera alone, and mixed with the proteus vulgaris. He also maintained a pure culture of the proteus. The result upon the proteus of growing in conjunction with the hog-cholera bacillus, was the evolution of a variety resembling the proteus mirabilis and proteus Zenkeri of Hauser.

Dr. Sternberg, of Washington, said that a few years ago every bacillus that differed a little in its action was considered a different species. Now we know that many are varieties of each bacillus. Whether the variations go so far as to produce species which will not revert, we do not know. He said that he had been much misled by this during his studies in Cuba.

Dr. William H. West, of Baltimore, said that the tendency now was to identify species of bacilli by morphological rather than by physiological characteristics. He said that the hog-cholera bacillus in the laboratories of Germany was probably a different species from that which had been under observation in Baltimore. He considered Dr. Smith's contribution valuable.

Dr. Smith closed the discussion.

The Effect of Various Metals on the Growth of Pathogenic Bacteria.—Dr. Meade Bolton, of Baltimore, said that some metals seem to have no influence upon the growth of the bacteria, while others have a more or less marked inhibitory action, as shown by a broader or narrower clear zone around the pieces of metal on plates otherwise crowded with colonies of bacteria. Just outside the clear zone, whether this is broad or narrow, there is, in nearly every case, a zone of intensified growth where the colonies are thicker than on other parts of the plate.

In the few tests as yet made for this purpose, there was entire absence of living bacteria in the clear zones. Inoculations from the clear zones remained sterile.

In some cases there are three zones around the metals, viz.: A clear zone immediately surrounding the metal; a zone of intensified growth, and a second narrower zone where growth was inhibited. It has been possible to detect in the medium, by chemical reagents, the presence of traces of those metals that exert inhibitory power. The solution of the metals in the nutrient medium takes place independently of the growth of bacteria, as it is possible to detect the presence of the metals in sterile media in which they have been placed, after they have lain for a few days, at any rate. A discoloration of the medium surrounding the metal, often makes a special test unnecessary.

Some metals have a much more powerful inhibitory action than others, as is shown by the broader clear zone. There is also some difference in the different bacteria with one and the same metal.

Some of the metals that have been tested were absolutely pure; others were commercial metals, marked chemically pure, and a few were either impure or alloys. Silver has a marked action. Hence silver wire sutures are less apt to give stitch abscesses than sutures of other material.

Notes on the Observation of Malarial Organisms, in Connection with Enteric Fever.—Dr. W. Gilman Thompson, of New York, called attention to the possibility of a double infection with malarial and typhoid germs. A typical case of typhoid fever lasting fifty-five days, with eruption, tympanites, and hemorrhage from the intestine, complicated by chills and hyperpyrexia, during the third week, with appearance of malarial organisms. Two other typical cases of enteric fever, with the observation of malarial organisms, which appeared in connection with chills during convalescence. Rarity of the mixed infection in the vicinity of New York, which is common in the South.

Dr. Osler, of Baltimore, said that chills in typhoid were common apart from malaria. He exhibited a chart of the only case of this mixed infection that had been seen at the Johns Hopkins Hospital. He related a case of mixed infection of pneumonia and pneumia.

Dr. F. P. Kinnicutt, of New York, related a case which was mistaken for typhoid, but which was proved to be malarial.

Dr. G. L. Peabody said that chills in typhoid were sometimes pyæmic, and these were of more importance.

He believed that the frequency of "typhomalaria" was exaggerated by many.

Dr. E. G. Janeway, of New York, said that he had often seen chills in typhoid due to the administration of antipyretics.

Dr. Sternberg, of Washington, said that the so-called "typhomalaria" was not such as was shown by the author, but cases which, being mistaken for malaria, afterward turned out to be typhoid. The physician, to save his reputation, added his final diagnosis to his provisional diagnosis.

Dr. J. C. Wilson, of Philadelphia, said that the name "typhomalaria" was unfortunate, in that it interfered with prophylaxis in typhoid cases.

Dr J. H. Musser, of Philadelphia, reported a case of mixed infection of scarlatina, measles, and intermittent fever.

Dr. H M. Lyman, of Chicago, and Dr. W. T. Councilman of Boston, reported cases bearing on the subject.

Dr. F. C. Shattuck, of Boston, said that chills in typhoid might be due to phlebitis of inaccessible veins.

Dr. J. C. Reeves, of Chattanooga, believed in a fever intermediate between typhoid and malaria.

Dr. George Dock, of Ann Arbor, had made autopsies on many cases of typhomalarial fever, and had found typhoid lesions.

Dr. Thompson closed the discussion by emphasizing the importance of examining the blood of fever patients for malarial organisms.

Experiments in Artificial Melanosis.—Dr. George Dock, of Ann Arbor, Mich , read a paper with this title. Investigations in cases of malarial fever with great pigmentation, show some departures from the changes that have been described as the result of injecting finely powdered substances (cinnabar) into the circulation. The object of the present series of experiments was to control the older observations, and to observe especially the behavior of the various kinds of leucocytes, as known by modern methods, to the foreign bodies. The animals used are dogs and rabbits; the substance injected, lamp-black suspended in normal salt solution. At this time the experiments are not finished, but have gone far enough to say that the changes found are not identical with those in malaria. The greatest difference is the slight participation of the macrophages in the experimental cases, as compared with malaria. The other observations as to the localization of the pigment were confirmed.

Some of the Chemical and Bacteriological Characteristics of Milk.—Dr. Thomas M. Rotch, of Boston, dwelt upon the importance of reaction in milk, in infant feeding. By feeding cows on sugar-beets in addition to other food, the milk was rendered alkaline. Alkaline milk is more like human milk than that usually obtained. Cows milked under antiseptic precautions gave the following results: First half of milking showed bacilli. Milk drawn with a sterile cannula was practically sterile. Hence the conclusion is drawn that the bacilli came from the tract between the udder and the end of the teet. In this way sterile milk is obtainable.

Dr. F. Forchheimer, of Cincinnati, O., said that the extreme importance of the subject merited further investigation.

Dr. T. Smith, of Washington, agreed with the author.

Dr. Rotch closed the discussion.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Forty-fourth Annual Session, held in Philadelphia, May 15, 16, and 17, 1894.

First Day, Tuesday, May 15th.

The Society was called to order by the president, Dr. H. G. McCormick, of Williamsport, Pa. After an opening prayer by Rev. A. B. Philputt, an address of welcome was given by Hon. Edwin S. Stuart, Mayor of Philadelphia. He recalled the fact that the first hospital for the treatment of the sick was inaugurated in Pennsylvania on the application of Benjamin Franklin, and was erected in Philadelphia, and from that time until now it has been doing excellent work. The first medical school and the first school of anatomy were also located in Philadelphia. Some time ago the city contained many colleges which were a disgrace to it, but those have now been wiped out,

The address of the Mayor was followed by one of welcome by Dr. E. E. Montgomery, of Philadelphia, chairman of the Committee of Arrangements.

Reports were made by the secretary, Dr. William B. Atkinson, and the Treasurer, Dr. G. B Dunmire. Dr. Atkinson said there were now fifty county medical societies in good standing, and that the State Society had at present two thousand five hundred members. The treasurer reported a total of $4,122.24 received for 1894. and expenses amounting to $2,423.45.

Dr George M Gould then presented a resolution calling upon the Legislature of Pennsylvania to adopt the law for the prevention of blindness in infants, recommended by the Committee of the Section on Ophthalmology of the American Medical Association adopted by the Legislature of the State.

Address in Surgery.—Dr. G. D. Nutt said success in many operations is often modified by the time when and place where such operations have to be performed. A great responsibility rests upon the family physician in many of those diseases of a purely surgical nature or tending that way. He is usually the first to see these cases; and unless an early surgical consultation is called, the time may pass when an operation can be safely performed. Many fallacies are taught in our text-books that have been proven false by modern surgery, which the general profession are slowly but surely accepting.

Modification of Pirogoff's Amputation.—Dr. F. Le Moyne read a paper with this title, advocating the preservation of the malleoli and the excavation of the retained section of the calcis at a point to correspond with each malleolus, with the object of gaining about three-fourths of an inch in the ultimate length of the limb, and procuring more accurate and permanent coaptation.

Psoriasis.—Dr. George V. Shoemaker showed cases illustrative of the etiology of psoriasis. Two of the cases were frankly rheumatic, two probably of arthritic tendency, and the fifth was the subject of chronic gastro enteritis. Dr. Shoemaker explained that psoriasis is often excited by the presence of rheumatism or gout, while in other cases it depends upon chronic disturbance of the digestive organs, disease of the liver, disorders of the blood, and maladies of the nervous system. He also explained that the appearance of the papules, patches, and scales, is characteristic and typical, whatsoever the cause. The facts relating to its etiology are most significant guides to treatment. In each case we must endeavor to ascertain the origin. Though the lesions present exactly the same appearance, the therapy must obviously differ in accordance with the etiology, and routine treatment of psoriasis is an impossibility. The defects of digestion and nutrition must be corrected; constitutional and approximately specific remedies must be administered, or the state of the nervous system must be improved. The habits of the diet must be regulated or changed. The Doctor asserted that ingestion of thyroid glands is a mode of therapy serviceable in certain cases. The grand principle of treatment is to determine the origin of each case. Acting upon this belief the Doctor lays comparatively little stress upon topical treatment. Dr. Shoemaker said that increasing experience convinced him that accuracy in tracing the genesis of the disease pointed to an internal therapy, upon which could be placed the reliance of the profession more firmly than upon local measures.

Organic Stricture of the Urethra.—Dr. Orville Horwitz, in a paper with this title, called attention to the fact that dilatation should be employed in all cases of recent strictures which are dilatable, occurring in any portion of the urethra, and which are not either resilient, irritable,

or nodular. This treatment is by far the safest in persons suffering from disease of the heart or kidneys, or diabetics who are broken down in health, who are suffering from debility, or who are advanced in years.

Continuous dilatation was recommended as an adjunct to other more radical means of treatment. It should be employed in tight strictures of the membranous portion of the urethra, complicated with retention of urine, and in those cases where the stricture is of small calibre, when located in the fixed portion of the canal; the patient is thus enabled to pass water with sufficient ease to allow him to be prepared for radical operation.

Modified rapid dilatation was advised for the treatment of filiform strictures, situated in the neighborhood of the bulbous and membranous portions of the canal, which are neither irritable, nodular, nor resilient, and which cannot be treated by gradual dilatation.

Internal urethrotomy should be limited to well-organized strictures, situated within from three and a half to four inches from the meatus.

Strictures at the meatus, or in the neighborhood of the fossa navicularis, should be divided on the floor of the urethra, especially if they give rise to reflex symptoms.

Dilating internal urethrotomy should be limited to strictures that are well organized and of long standing, within from three and a half to four inches from the meatus, which are nodular or resilient.

This operation should not be performed on those who suffer from impotence, neurasthenia, nocturnal emissions, or sexual hypochondriasis.

In these cases ordinary internal urethrotomy, by the Gross instrument, is advised. Combined internal and external urethrotomy is commended in nodular strictures of the penile portion of the urethra, and in strictures of the bulbous portion of the canal. External and internal urethrotomy, with or without a guide, is advised under the usual conditions.

Electrolysis was not recommended.

Cramming in Medical Schools.—Dr. Oscar H. Allis, surgeon to the Presbyterian Hospital, stated that the lengthening of the term of study of medical schools had increased the number of professors, many of whom were not authors, and this made note taking indispensable. That as there was no time for the student to do this, it made it imperative that he place himself under a quiz master throughout his entire course. That between lectures, laboratory work, hard work, demonstrations, clinics, and quizzing, he must put in between sixty and seventy hours a week. The average class room work in schools, colleges, and seminaries, he said, was three hours a day for five days. The speaker complained that men in medical schools were compelled to take a three or four years' course, spend hard-earned or borrowed money for lectures and maintenance, and be "plucked" at the last moment. Every man in the seminary or school who is diligent and moral gets his degree. Ten per cent. of the medical students fail. If a rigid entrance examination were instituted, many of those who fail would be arrested at the outset.

It was urged that some return should be made to those who fail; that if medical schools were compelled by law to return the fees for instruction, the number of graduates would not be diminished, but the ten per cent. who now fail would stand on a different footing. Such a course would compel medical schools to compare their requirements, their methods, and courses of study, with other institutions of learning. In literary institutions class-room work counts more than final examinations. In medical schools the professor knows little of the student, class-room work has little influence, and the final examination decides the fate of the applicants. Dr. Allis declared that good, faithful men are thus often sacrificed.

Second Day, Wednesday, May 16th.

Election of Officers.—The session was called to order by the president, and the report of the Committee on Nominations was announced as follows: *President*, John B. Roberts, of Philadelphia; *First Vice-President*, Dr. S. C. Stewart, of Clearfield County; *Second Vice President*, Dr. J. A. Lippincott, Allegheny County; *Third Vice-President*, Dr. J. H. Wilson, Beaver County; *Fourth Vice-President*, Dr. R. Armstrong, of Clinton County; *Secretary*, Dr. William B. Atkinson, of Philadelphia; *Assistant Secretary*, Dr. H. G. Critzman, of Franklin County; *Treasurer*, Dr. G. B. Dunmire, Philadelphia County; *Delegates to New York State Medical Society*, Dr. I. W. Groff, Montgomery County; *New Jersey Society*, Dr. C. A. Rahter, Dauphin County; *Maryland Society*, Drs. A. C. Wentz, of York, and P. R. Kcons, of Cumberland County.

Address in Medicine.—Dr. W. S. Foster, of Pittsburg, read the annual address in medicine. He said that recent advances in medical practice have been the crystallization of therapeutic measures by slow processes as compared with the picturesque leaps and bounds that have characterized surgical practice, and that tuberculin and cerebrin have been equally fatuous attempts at rapid advance; the first, a legitimate and therapeutic attempt, the last, a palpably fraudulent scheme. The recurring popularity of calomel and other mercurial compounds and renewed use of digitalis in the continued forms was commented upon. Pure oxygen was recommended as worthy of trial in pneumonia where the respiratory area is greatly encroached upon. The routine use of antipyretics was condemned as irrational. In the use of anæsthetics, Syme's principles were mentioned as being again recognized as the correct ones for the guidance of the physician. Ether was declared equally as dangerous as chloroform, while its after-effects upon the emunctory organs, it was asserted, make it an agent to be used with the greatest caution.

Christian Science in its Relation to the Medical Profession.—Dr. Hildegarde H. Longsdorf, of Carlisle, read a paper with this title. The subject, he said, was more important than it might at first sight appear, even contemptible, yet from the proneness of the uninformed to exaggerate and mystify disease all remedial agencies carry with them an overpowering influence, and to the younger practitioner especially are baffling and vexatious. Christian science was probably the most pretentious and certainly the most successful of the outgrowths of our modern high-pressure civilization, which, not content with its acknowledged empire over material nature, must enter the realm of psychological phenomena and call upon a too credulous public to believe what it cannot explain and revere what it cannot comprehend. There have been many such mock systems in former years. Christian science, however, goes a step beyond any of its forerunners, is one shade finer and more plausible in its theory, and more conspicuously successful than any similar intellectual epidemic the world has ever witnessed. These fatuous misbeliefs are the intellectual scandal of the age, and it becomes a puzzling question how to regard those who honestly believe in them, and what should be the attitude of the physician toward those who aspire to the office of healer.

If it were not for the fact that the doctrine is rapidly spreading, gaining friends and influence among the most intelligent classes, the subject might well be dismissed with a smile as one more of the numerous phases in which the ever-restless mind has manifested itself. But it has a vast and increasing power, and not only among the uneducated. It has its representative literary journals, and an array of special agents or missionaries, a respectable showing of institutions or metaphysical colleges, and a vast number of private establishments for the cure of every disease under the sun.

The question arises, how are we to regard it and how we are to be armed against its inroads? It would be out of place to argue against mental cures, and it would be idle to deny the power of mind over the body, but the fact remains that the process cannot be rationally explained so that the subjects of it can clearly understand it.

Consequently, in endeavoring to maintain our professional self respect we are in danger of becoming illiberal, narrow minded, and dogmatic. The importance of some definite restraining force for these abuses can scarcely be overestimated, and if public opinion and the advanced philosophical science of our era have been powerless to effect this, it would seem to come into the province of legislative enactment.

Should the Journal of the American Medical Association be Used to Promote Quackery?—Dr. S. S. Cohen read a paper with this title, which was an arraignment of the trustees of the *Journal of the American Medical Association* for persisting in publishing advertisements of secret nostrums, contrary to the unanimous resolution of the association in 1892.

After Dr. Cohen's remarks a series of resolutions forwarded to the State Medical Society by the Philadelphia County Medical Society, urging that action be taken to have such unethical advertisements excluded from the *Journal of the American Medical Association* were discussed. These resolutions have all been printed in various journals to which they were sent at the time of their original adoption by the Philadelphia County Medical Society.

Dr. Thomas then offered a resolution, which was adopted, that the resolutions of the Philadelphia County Medical Society on this subject be sent to each trustee of the Journal and that the delegates of the Society be instructed to present them at the meeting of the American Medical Association in San Francisco next month, and that the trustees be informed that it is the sense of this Society that they would prefer to have the publication of the Journal discontinued if the money received for such improper advertisements is requisite for its continuance.

A resolution was adopted also to the effect that if the funds of the association will not permit the Journal to be published without a violation of the code of ethics, the trustees cease it publication.

Croup and Diphtheria.—Dr. B. H. Detwiler, of Williamsport, spoke of the pathology and treatment of membranous croup and dwelt largely on the importance of an early diagnosis of it from the croup of diphtheria. Dr. Detwiler asserted that diphtheritic croup has a mortality of sixty to eighty per cent. and that the phlogistic treatment which he advised had absolutely no mortality record. He dwelt upon the duality of the two diseases, making the anatomical construction of the ciliated epithelium tissues of the vocal dorus and the squamous epithelium of the pharynx and fauces and their inflammatory products the diagnostic signs of duality. His plan of treatment is to produce free depletion by leeches after cyanosis begins, with revulsion by cantharidal blisters and calomel in quarter-grain doses every half hour till the spinach stools are voided.

The Operative Treatment of Muscular Asthenopia (Heterophoria).—Dr. Charles Hermon Thomas read a paper with this title. A number of illustrative cases were reported which showed the extremely varied character of the symptoms and the favorable results of operation. The subjective symptoms of asthenopia show almost no distinct characteristics pointing to their origin, whether refractive or muscular; the same headaches and the same sense of eye strain are complained of under both conditions. Graduated tenotomy (partial) is practicable and efficient because of the elasticity of the margins of the tendons. Muscular asthenopia may present symptoms of all grades of importance, from the slightest to the most serious. As in refractive, so in muscular asthenopia the gravity of the symptoms bears no constant relation to the amount of the physical defect or muscular error. As much—and very much the same kind of—relief is to be expected from the correction of muscular anomalies as from the correction of errors of refraction and accommodation, as might be expected from the similarity in the symptoms. The muscular condition in every case should, as a matter of routine, be as carefully investigated as are the media, eye ground, the refraction, and the amplitude of accommodation.

An Epileptic Colony.—A resolution was offered and adopted that it is the sense of the Medical Society of the State of Pennsylvania that an epileptic colony should be established for the benefit of those epileptics whom the commonwealth is obliged to support, and for others supported by their friends. Copies of this resolution to be sent to the governor, speaker of the House, and president of the Senate, and to the president of the State Board of Charities.

Dr. H. G. McCormick, president of the State Board of Examiners representing the Medical Society of the State of Pennsylvania, announced that the first examination under the new law for license to practise in Pennsylvania would be held on June 11th, in Philadelphia and Pittsburg respectively, the same questions being given to all applicants at both cities.

A resolution was adopted urging Congress not to diminish the usual appropriation for the support of the Library of the Surgeon General's Office at Washington.

Address on Mental Diseases.—Dr. T. M. T. McKennan, of Pittsburg, read the Annual Address on Mental Diseases. A statement was made of the progressive advancement in hospitals for the insane, and especially in the education and training of nurses. The toxic origin of many of the insanities was dwelt upon and especial attention called to auto-intoxication as a factor in the etiology of insanity. The influence of gynecological operations and pelvic diseases in women in causing insanity were touched upon. The relation of syphilis to general paralysis of the insane was dwelt upon, and the great probability, amounting to almost positive proof, of the syphilitic origin of general paralysis. Trianol and duboisine were spoken of as two new hypnotic agents of value, and electricity as a valuable therapeutic agent.

Studies in Obstetrics and Gynecology.—Dr. Anna M. Fullerton in this paper presented her views as to the most frequent causes of pelvic disease, and the resultant decrease in the child bearing capacity of civilized women. The opinions advanced were founded upon the observations made by her during eight years of service as physician in charge of the Woman's Hospital of Philadelphia. The teaching that the majority of pelvic diseases are of microbic origin was upheld; and the vulnerability of the woman of the day to such diseases was shown to be the result of general debility of all the tissues in consequence of the physical and mental strain induced by the habits and requirements of modern life.

The remedy for this evil was felt by the writer to lie in a clearer understanding of the laws of reproduction as affected by the changed conditions of civilization; and especially in the higher education of women, in order to give them a proper appreciation of physiological and educational laws, and thus better fit them to act as guardians over the pre natal as well as the post natal influences affecting the well-being of the child.

Whooping-Cough.—Dr. W. C. Hollopeter spoke of the need of a specific for this specific disease, for as such he regards it. He said that by most authorities this disease was regarded as the most fatal of all the diseases of children under one year of age. This fatality is not limited to the first year of life, but continues to manifest itself long after this period in broken health of all kinds referable to the respiratory, intestinal, as well as the various glandular organs. The speaker placed considerable value on the peculiar puffiness of the mucous membrane of the eyes and the swollen or œdematous condition of the whole of the face, almost dusky; this condition may exist for days before the catarrhal symptoms have extended throughout the respiratory mucous membrane. The cough at this stage may not be at all suggestive—it may be, in fact, purely bronchial. This symptom of fulness about the eyes, which is quite as constant in measles as in pertussis, and with measles it is closely associated and must be differentiated. As measles are diagnosed by the appearance of the eruption first on the

hard palate, so, he contended, whooping-cough may be diagnosed in its earliest stage by the characteristic swollen condition of the eyes and face. He insisted upon this factor as of the greatest importance, as its recognition will enable the physician to institute specific treatment early, when the disease is yet local and may be brought more speedily under control. The drugs he has found most efficient in the catarrhal stage have been hydrogen peroxide in sterilizing the naso-pharynx, and assafœtida occasionally used for the paroxysms. Belladonna also is to a high degree beneficial in young children, and should be placed first. This he pushes until toxic effects are secured, when less suggestive characteristics of the cough are observed.

Amputation near the Ankle.—Dr. G. G. Davis, of Philadelphia, showed four cases of amputation in the neighborhood of the ankle as a protest against abandoning these operations in favor of amputation below the knee. The first case was a Chopart amputation of thirteen years; never any trouble wearing a shoe made by a common shoemaker. The second was a Chopart with apparatus, showing no deformity, and walking well with scarcely a perceptible limp. The third was a Pirogoff with apparatus, walking well. The fourth was a double amputation in a man weighing two hundred and twenty pounds. One leg was removed below the knee—seat of election—and the other a Pirogoff. The patient stated that the Pirogoff was much the more satisfactory.

It was held that in none of these cases would their condition have been improved by an amputation high up on the leg.

Third Day, Thursday, May 17th.

Address on Hygiene.—Dr. J. H. Wilson, of Beaver, read the Annual Address on Hygiene. He spoke of the reduction in the amount of sickness, and attributed it to the increased number and improved efficiency of the boards of health. In speaking of the practice of free school supplies prevalent throughout the State, Dr. Wilson said: There is not a pretence to give the scholars the same books and pencils as the day before, and from the habit of children chewing lead pencils, diphtheria and other diseases may be transmitted. There should be some method of disinfecting the books. It would be much better for the child to be supplied by the parent than to take the risk under the present method. Some school boards need to be taught that foul air is heavier than pure air and cannot be gotten rid of by ventilators at the top of a room. Dr. Wilson went on to speak of the physician's duty in instructing those of the masses who come under his care in the simple laws of hygiene, such as removing all the day clothing when retiring for the night, and washing the entire body every day. Electricity, he said, is becoming recognized as a scientific agent. It has been experimented with in purifying atmospheric dust and in disinfecting sewage. In speaking of tuberculosis, Dr. Wilson said: The annual mortality by this disease in this country is 165,600, or an average of 450 a day. Dr. Fletcher's labors in this city have attracted much attention. He has proven that certain residences in this city, in the Fifth Ward, are infected by this disease. In the discussions which followed, Dr. William P. Munn, of Denver, said: We have in Denver a house to-house inspection, conducted by a trained sanitary inspector. The inspection consists not only of the house and its immediate surroundings, as the pavements and the alleys and sewers, but also the habits of its inmates. The results of these inspections are classified and indexed in a manner similar to cards used in libraries. Anyone contemplating buying a house can go to the Health Board and have this information spread out before him, and see the condition of the house. Many people are in this way saved by the records of the Health Department from buying infected houses. "And, in many instances, negligent landlords, knowing that their properties will not be rented while they are down in the health records as bad, have them put in a healthful condition."

Prophylaxis in the Treatment of Tuberculosis.—Dr. Lawrence F. Flick, of Philadelphia, in his paper with this title, asserted that a most valuable lesson taught by the organic theory of tuberculosis is prophylaxis in the treatment of the disease. Tuberculosis is strictly a parasitic disease. In nature's effort to get rid of the parasite, reinfection is liable to take place.

Were it not for reinfection, all cases of tuberculosis would get well. The disease is really a series of invasions of the organism producing it.

The prevention of auto-inoculation gives the key to the treatment of this disease. In so far as this can be accomplished, treatment is successful, and no farther.

Auto-inoculation can be controlled in two ways: by building up the system of the patient so as to enable it to resist new deposits, and by preventing the readmission of the organisms into the system.

Strychnine in Pulmonary Consumption.—Dr. Thomas J. Mays, of Philadelphia, in his paper with this title, claims that, next to rest and food, strychnine in large doses is the most important agent in the treatment of pulmonary consumption. Begin with $\frac{1}{30}$ of a grain, and gradually increase to $\frac{1}{15}$, $\frac{1}{10}$, or $\frac{1}{8}$ of a grain, or even give it in larger doses, four times a day. According to the author it does not produce albuminuria or diabetes, as is generally supposed. It alleviates the loss of appetite, the vomiting, the constipation, the nervousness, and sleeplessness, the pain in the chest, the cough and expectoration, the dyspnœa, the weakness of the heart, and acts as a blood-builder in an eminent degree. Its usefulness rests on its influence over the nervous system, and is another link, the speaker said, in the chain of evidence, which shows that, in the great majority of cases, pulmonary consumption is the direct result of primary disease of the pulmonary nerve-supply.

Tubercular Meningitis.—Dr. Daniel Longaker, of Philadelphia, in a short paper emphasized the frequency of tuberculosis of the mediastinal glands; the occasional dissemination of acute tuberculosis from such foci, sometimes general, but usually more limited—in the case in question, to the cerebral meninges and the spleen. It may be latent, but frequently causes long-continued cough, and such cough, if associated with even slight impairment of the general health, should be looked on with suspicion. In adults the general health may be perfect. It must be regarded as a menace to the life of the individual, although under favorable conditions it produces no harm in the majority of cases. A mass of authiakosis in the cheesy gland, near the bacilli, seemed to prove inhalation as the origin of the disease.

Colorado Climate for Consumptives.—Dr. Wm. P. Munn, of Colorado, said that tuberculosis of the lungs is curable. He spoke of climatic environment as the greatest factor in the battle of the human organism against micro organism. He said that the climatic advantages of Colorado are: 1. Its low absolute and relative humidity. 2. Rarity of atmosphere dependent upon altitude. 3. Sunshine. 4. Cool and equable temperature.

The great majority of cases of consumption if sent to Colorado, will recover, if only sent early. Hemorrhagic types of the disease are especially benefited. Residence in Colorado should be permanent, if possible, but in no case less than five years.

Early recognition of pulmonary consumption is essential to its successful climatic treatment. The healthy children of tubercular parents now coming to adult life in Colorado are a strong argument against the heredity of consumption. Favorable climatic environment protects them from the direct contagion of their parents due to residence in the same home.

A Bureau of Public Health.—A resolution was offered and adopted that the society expresses its approval of the establishment of a bureau of public health, and its opinion that the welfare of our country would be greatly benefited thereby, and requests that the representatives of

our State aid the passage of the bill in Congress by their earnest efforts. A copy of the resolution was ordered to be sent to each Senator and member of the House of Representatives at Washington.

Address on Ophthalmology.—Dr. George E. de Schweinitz, of Philadelphia, divided the art of restoring health to disordered eyes into optical, surgical, and medical therapeutics. After a brief review of the most important advances in the first two departments of this division, he addressed the Society on the medicinal and non-surgical ocular therapeutics. He reviewed subconjunctival injections of corrosive sublimate, commending them in selected cases, and described his experimental work and that of Dr. Chasseaud in connection with intraocular injections of antiseptic substances, concluding that this form of medication, although presenting attractive features, had not yet reached a safe status in ophthalmic practice.

Abuses of mercury in the treatment of diseases of the eye were referred to, and, in the management of optic nerve atrophy, suspension, injections after the manner of Brown Séquard, and the effects of various drugs, particularly antipyrin, strychnia, and nitro-glycerine were described.

The relation of electricity to diseases of the eye received attention, especially the method of treating optic nerve atrophy by means of voltaic alternatives, and the use of the continuous current in the management of vitreous disease and chronic irido-choroiditis.

The medicinal treatment of the congested choroid coats, as the result of eye-strain, was insisted upon as an essential aid in the management of asthenopia. Following this, modern investigations in regard to the untoward effects of cocaine were discussed, the new mydriatic, scopolamine, was compared with atropine, and the address closed with a reference to the proper method of procuring conjunctival antisepsis, as nearly as this is possible, and the danger of powerful germicides in relation to the cornea.

Dr. de Schweinitz closed with a strong appeal to each physician to use his personal influence to assist in securing legislative regulations for the prevention of blindness from ophthalmus neonatorum.

Treatment of the Corneal Ulcer by General Practitioner.—Dr. S. Lewis Ziegler asserted that corneal ulcer is not necessarily dangerous, but may seriously impair vision, especially when central. Lachrymo-nasal lesions are the immediate cause, gastro-intestinal disorders from errors in diet are the remote cause; constitutional dyscrasiæ may have some influence as a predisposing cause. If septic materials are present in the ocular cul de sac, a break in the corneal epithelium will court infection and subsequent ulceration.

To summarize: Simple corneal ulcer is a purely local inflammatory process, arising chiefly from infection by septic secretions, and originating in lachrymo nasal lesions.

The treatment required is: 1. Apply a mild antiseptic, soothing lotion to the eye, a mydriatic if needed, and hot applications when indicated. 2. Treat the nose locally with compound tincture of benzoin and the use of a cleansing spray. 3. Regulate the diet, give salt-water baths, and improve the hygiene generally.

Uterine Fibroids.—Dr. Charles P. Noble, in a paper with this title, referred to the teaching concerning fibroids current ten years ago, viz.: 1. That the disease is a benign one, tending to a spontaneous cure at the menopause. 2. That it never causes death. 3. That hysterectomy is the most dangerous operation in surgery, having a mortality of forty per cent. He pointed out that ten years' study of the disease has demonstrated: 1. That it is a serious disease, almost invariably producing marked invalidism, and not infrequently causing death by hemorrhage, by undergoing malignant, cystic, or necrotic changes, by paving the way for intercurrent diseases, by proving an obstruction to labor, and by pressure upon the urinary organs and other abdominal viscera. 2. That the menopause is delayed from five to ten years. 3. That spontaneous cure not infrequently does not follow the menopause, and that many fibroids grow more rapidly after than before that period. 4. That hysterectomy, except in complicated cases, has been a comparatively safe operation. He quoted the recent experience of Kelly, Baer, Polk, and himself in hysterectomy—including all classes of cases as they come, one hundred and sixty-eight cases, nine deaths, or a mortality of five and three-tenths per cent.

The deaths were in the broken-down complicated cases. The failure of ergot and electricity and the comparative failure of oöphorectomy to cure was referred to. The principle of early operation, now accepted for ovarian tumors, was urged in the treatment of fibroid, so that the mortality can be still further reduced.

A Cause of Failure in the Surgical Treatment of Internal Strabismus.—Dr. Thomas F. Hansell, in his paper with this title, said that Donders' theory of the causation of internal squint in hypermetropia is incomplete, in that he taught that the excessive action of the accommodation in overcoming hypermetropia induced corresponding excessive convergence only; whereas its influence is not thus limited to the interni, but extends to all the muscles under the control of the third nerve. Dr. Hansell believes that the simple, pure, internal strabismus of hypermetropia, as described by Donders, cannot exist, but must always be complicated by an upward strabismus, for the following reason: The stimulus of the overacting ciliary muscle is communicated not only to the nucleus of the internus, but to that of the superior rectus, of the inferior rectus, of the inferior oblique, and of the pupil.

The nucleus of the levator palpebræ is probably also involved; but since the function of this muscle is to elevate the lid, and not to rotate the cornea, its action is not relative to the subject of this paper. Hence their combined action is:

1. Contraction of the pupil.

2. Esotropia, because the external rectus, the antagonist of the internal, receives no motor impulse.

3. Hypertropia, because the two elevators of the cornea, the superior rectus, and the inferior oblique, overcome by their contraction the single depressor, the inferior rectus, which is the only one of the depressors belonging to the third nerve group, the superior oblique having an independent nerve supply.

Therefore,

1. The squinting eye is invariably rotated inward and upward.

2. In alternating squint, fixation is transferred from one eye to the other at the patient's will, and the non-fixing eye immediately turns inward and upward. Fixation with R. means left hyperesotropia. Fixation with L. means right hyperesotropia.

3. In constant squint, fixation is always made with the same eye; hence there is no transference of either esotropia, or hypertropia, and the eye not used in fixation is rotated inward and upward.

4. In concomitant squint, binocular vision is established by correction of the refraction and tenotomy of both internal muscles.

5. In constant squint, in addition, vertical equilibrium must be restored by tenotomy of the superior rectus of the squinting and possibly of the inferior rectus of the fixing eye.

The President-elect, John B. Roberts, of Philadelphia, was introduced by Dr. McCormick. He took the chair, and announced the appointments for the annual addresses of next year as follows: Address on Medicine, Dr. I. C. Gable, of York County; Address on Obstetrics, Dr. W. B. Ulrich, of Delaware County; Address on Surgery, Dr. C. L. Stevens, of Bradford County; Address on Hygiene, Dr. Hildegarde H. Longsdorf, of Cumberland County; Address on Mental Diseases, Dr. F. X. Dercum, of Philadelphia County; Address on Otology, Dr. L. H. Taylor, of Luzerne County.

Correspondence.

A QUESTION OF FACT AND ACCURACY IN STATISTICS.

DR. SPENCE TAKES ISSUE WITH DR. BECK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: My letter in your issue of June 2d, which seems to have aroused Dr. Carl Beck to an unusual degree, as evidenced by his reply in your issue of June 16th, was not intended as a discussion of the doctor's paper on pyothorax. It was written simply to correct the false conclusion which he drew from my article in *The St. Louis Clinique*.

I am sorry, after aiming to make my remarks very easy of comprehension, he should, besides misinterpreting so many of its statements, consider the letter as an attack upon himself. These are hardly of sufficient consequence that I should take up your space to convince Dr. Beck of his errors; but I must, in justice to those concerned, reiterate those statements of mine which the doctor has directly contradicted.

I was present at the meeting of the County Medical Society the evening Dr. Beck read his paper, and I state again, "the general opinion was, that free incision with good drainage was all that was necessary in the majority of cases." Dr. Beck evidently forgot that four men discussed his paper, and only one (one of the surgeons he mentioned) was mildly in favor of resection. It seems to me, therefore, the general opinion was as I have stated.

Dr. Beck refers to a patient on whom he says he "unhappily had the bad fortune to be compelled to perform resection" after Dr. Ripley had made an incision. It will be my good fortune, while assuring him of my sympathy, to give the doctor here the true history of that case. I am surprised to find that it differs so materially from the one published by Dr. Beck, for this appears to be Case IX. of his paper.

The child, a girl of six years of age at the time of the operation, not ten as published, was taken sick in March, 1893, with pleuro pneumonia. Dr. Ripley, in private practice, saw the child in consultation with the family physician, and diagnosed an empyema.

On April 4, 1893, Dr. Ripley made a free incision into the chest, and after liberating a large quantity of pus, introduced a good sized drainage tube, dressed the wound, and gave the necessary instructions. He only saw the child once more, and that was four days after the operation. On April 14th, ten days after the incision, the family for some reason became displeased with their family physician and dismissed him. That of course ended Dr. Ripley's observation of the case. Another physician was now called, who on the advice of another consultant, sent the child to St. Luke's Hospital, under the supposition that the other pleural cavity also contained pus. Tnis proved to be incorrect, for so the St. Luke's people decided after a careful examination including the insertion of an exploring needle. They found no pus in the chest into which they introduced the needle. Therefore, as the child was never in St. Francis Hospital or in any other except St. Luke's, contrary to Dr. Beck's report she was not "aspirated for empyema in a hospital of this city."

The last attending physician was recalled after the child had been sent home from St. Luke's Hospital, and by means of a chain saw he exsected a small piece of rib, and introduced a drainage-tube of very small calibre. This exsection was done about three weeks after the incision, and some time later a piece of this small tube broke off into the chest. It is ridiculous to say, as Dr. Beck does in his history of this case, this tube, "after it had courageously resisted the permanent rush of the retained pus, at last resigned and broke beneath the safety-pin," when you reflect that this pus cavity had been opened twice and was constantly draining during the previous three weeks.

Now on May 15, 1893, less than six weeks after Dr. Ripley's incision, instead of six months as he reports in his pathetic history, Dr. Beck exsected a piece of rib three eighths of an inch long. The parents showed me these curios, the piece of bone last exsected and the several drain-tubes, which they keep for safety in a little plush lined jewelry box.

Dr. Beck's report of this case now reads as follows: "Four weeks later recovery was perfect, after the poor child had been aspirated, incised, and resected, first with saw and then with shears." This reads well, but what are the facts?

The mother tells me the child was confined to bed during May, June, July, August, and into September, the next four months after Dr. Beck's operation, and the wound was not healed until Christmas, 1893. Thus, instead of recovery being perfect in four weeks, as Dr. Beck has the presumption to tell us, the child was four full months in bed, and recovery was not complete till seven months after Dr. Beck's resection.

These facts need no comments; but they show how valueless this case is as to the relative merits of incision and resection. It was a resection, following an exsection.

I have gone rather minutely into this history, in the hope that Dr. Beck will copy it into his case-book, so that he may have it at hand, should information be again requested of him. I really trust he has been more accurate in the histories he has published of the other cases.

Dr. Beck says in his letter, "The value of the fourteen histories which were appended to my reasons why resection is the better treatment, consists in their unusual and interesting additional circumstances." It must be admitted they are both unusual and interesting, especially Case IX. It is very unusual, even after, according to Dr. Beck, the irrational operation simple incision, to have fistulæ remain as long as in the case twenty-six years of age, mentioned in his paper, and in Cases III., V., and VI. Certainly Cases V. and VI. cannot be cited as very encouraging examples of the "only rational method of treating empyema." Surely the doctor does not give to resection the credit for the recovery of Cases XII. and XIII.; for he says he did not operate on them at all, the first case having expectorated the pus, and in the other it was absorbed.

Statistics, in order to be valuable, should be as to their material facts, correct.

ARNOT SPENCE, M.D.

70 WEST SEVENTY-FIRST STREET, June 29, 1894.

A LARGE DOSE OF CYANIDE OF POTASSIUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the MEDICAL RECORD for June 9, 1894, I notice a criticism upon my report of a case in which a large dose of cyanide of potassium was swallowed without a fatal result.

I have just written to my patient of two years ago and enclose his answer. Since it is so naïve and corresponds closely enough to his first statement to me, with which I took care not to acquaint him, I hope you will print it entire, simply suppressing the signature.

In my opinion this letter of my patient is characterized by about as much "precision and exactness of detail" as we are liable to get in suicidal attempts.

If my critic has any cases in which large amounts of cyanide were weighed and recorded before being taken, I hope he will publish them. As a rule, however, this means of satisfying our laudable scientific curiosity is not taken by the suicide.

On the part of the doctor in this case, there has been no "guessing" at all, as I have simply reported the statements of the patient.

I am very sorry that my critic is dissatisfied with the definiteness of my report, but I have simply furnished

what I had to give, hoping that it might be of value to someone of my fellow-laborers.

Yours respectfully,
F. W. HIGGINS, M.D.

"SYRACUSE, N. Y., June 13, 1894.

"DR. HIGGINS—

DEAR SIR: Yours of June 11 at hand and in reply I went to a drug store and could not find just such a shaped piece of cyanide potassine as I took, but had to break it off of a large chunk, and it was rough and ragged and weighed nine grains. Now I think the piece I took was heavier, as it was about the same size but was a solid piece and perfectly smooth on all sides. I do not think it was possible for any of it to have remained in the glass, as it was a hard chunk, and I swallowed it immediately after drawing about one ounce of whiskey on it. Now, if you will draw up such papers as you want and send same to me I will go before notary public and swear to and save them. The date was October 7, 1892. Hoping the above will be satisfactory, I remain yours, and ready to do you a favor."

MUST THE PARSON PAY?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Periodically the question of "Must the Parson Pay?" is resurrected, and at this particular period it is viable again. This afternoon I have read an article from a Durham, N. C., doctor, and an answer from "A Minister," both of which are clear of the true inwardness of the question. Both speak of the amount of money received by each, respectively and relatively, and upon that base their respective sides of the argument. This is not the question at all. And there is one which, while very much lower than the highest, will appeal to the reason of even the Durham M.D. Indeed, he challenges the argument when he says that, when he had determined that those well-fed and well paid North Carolina preachers were no longer "objects of charity," and consequently not entitled to the doctor's largess, with a magnificent burst of generosity he increased his subscription to the minister's salary "from $39 to $50 per year." He "had been a member of the church for years," and, of course, was under obligation, according to his own showing, to pay for what he got in preaching. How well does he do it. Fifty dollars per year. Fifty-two Sundays in each of those years—two sermons each Sunday and one Wednesday evening at prayer-meeting, give an aggregate of one hundred and fifty six hours of his preacher's time devoted to the doctor's welfare every year, for which the doctor pays the munificent sum of thirty cents (in round numbers) for each hour's work. If the doctor hasn't a wife, he ought to have, so to the two the price is reduced to a little over fifteen cents for each; and when he says he has practised medicine at Durham for twenty years, it is at least presumable that the doctor has averaged during that time three children to hear each sermon. So that three cents is the figure at which his spiritual medicine comes to him per hour per head. And this takes no thought of the many kindly offices done by the good pastor to the parishioners with never a thought of compensation. Now, it seems pertinent to ask the doctor if, when he sends in the parson's bill, he will in the spirit of "the one for the other," which he so insists upon, fairly estimate his prescriptions at the same royal fees which he pays the parson. To a man up a very dwarfish tree, it looks, if he look with good eyes and fairly, that the parson is the one who "wears the yoke," and not the doctor, and if the parson should "rebel," preaching would come quite a good deal higher to the most of us than it does at present. "Objects of charity," indeed! If there is a man on earth who earns every dollar of his salary, it is the preacher of the gospel. True, the doctor earns his—true, the doctor does a great deal of his work for people who cannot pay; but it is also true that many members of the Durham church can't pay anything for their preaching, and others won't, so that this is only as broad as it is long. The doctor has appealed to the *quid pro quo* argument, and should be held to it. The fee for office prescriptions in smaller towns is usually $1. If the Durham doctors will, in local society assembled, proceed an other step in their reformation, and at next report be able to show that they each have raised their church subscription to $156 per year for each member of each family, then they will have earned the right to vaporize upon this question some more, and the preachers will make no objection to paying their medical bills like other folks.

For shame, my brethren! Blush to remember that you ever thought to say such things before, and don't ever do so again. I intimated that there was a higher and better reason than I have indicated for holding up the hands of these men, but I am no preacher, and the MEDICAL RECORD is no publisher of sermons. I am a practitioner of medicine, however, and I don't belittle my profession when I claim that we could do less well without the offices of the faithful, conscientious pastor than he without us. My pastor—God bless him—ministers faithfully to my living and has lovingly and tenderly buried my dead, and when opportunity offers I shall serve him, glad to be able to in some measure show my love and gratitude. Charity, indeed; God save the mark!

J. C. BOGLE, M.D.

DANVILLE, KY., June 11, 1894.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 30, 1894.

	Cases.	Deaths.
Tuberculosis	99	48
Typhoid fever	7	6
Scarlet fever	63	10
Cerebro-spinal meningitis	4	4
Measles	86	10
Diphtheria	232	61
Small-pox	9	4
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

New Laws of Interest to the Medical Profession.—The last Legislature was no exception to the average run of legislatures as to attempts made to break down the safeguards of the medical profession. One bill cut the fee for admission to the regents' examination from $25 down to $5; another made the State pay the fee instead of the student; and a third, in the interest of the Faith Curists, provided that any person may freely contract for the services of whomsoever he considers competent to alleviate suffering, or prevent or heal disease, and it shall be lawful for persons so employed to attend, treat, nurse, and endeavor to heal the employing patient and receive compensation therefor, subject to the medical laws of the State relative to improper practice. None of these bills were passed.

A law was passed providing that any person holding a diploma of date prior to January 1, 1880, conferring the degree of bachelor or doctor of medicine from a reputable incorporated American medical school or college, and who has been a resident and citizen of this State continuously since June 1, 1880, and who omitted or neglected to register with a county clerk as prescribed by law, shall, upon production of his or her diploma and satisfactory proof of such facts, as provided in section two hereof, be entitled, upon payment of a fee of $25, to receive from a State board of medical examiners recommendations upon

which the regents shall issue, under seal, a certificate of the facts that he or she may register in the clerk's office of the county where he or she may reside, which shall, after such registration, be a sufficient license to practise medicine in the county where registered. Proof of such residence shall be by affidavits of at least two reputable citizens, whose reliability shall be certified to by any county or supreme court judge of the State. Any person desirous of securing the benefits of this act must do so within one year from the date it takes effect; but it shall not be construed to conflict with chapter 661 of the laws of 1893, the Public Health Law.

The Governor vetoed an amendment to the Public Health Law providing that any person who, not being then lawfully authorized to practise medicine within this State and so registered according to law, shall practise medicine within this State without lawful registration, or in violation of any provision of this article, shall be deemed guilty of a misdemeanor, and on conviction thereof shall be punished by a fine of not less than $50 for the first offence, and for each subsequent offence by a fine of not less than $100, or by imprisonment for not less than 100 days, or by both fine and imprisonment. When any prosecution under this article is made on the complaint of any incorporated medical society of the State, or any county medical society of such county entitled to representation in a State society, the fine when collected shall be paid to the society making the complaint, and the expense incurred by any such society in such prosecution, including necessary counsel fees, may be retained by such society out of the penalties so collected, and the residue, if any, shall be paid into the county treasury. In vetoing this bill, the Governor said: "The Public Health Law was constructed upon the principle of excluding from its provisions all but civil penalties, and transferring all criminal penalties to the penal code, where they properly belong. It was with this idea that the Statutory Revision Commissioners, in revising the health laws, omitted from the Public Health Law enacted last year the penal provisions which this bill contains, with the intention of inserting them in the penal code. As it happened, the Legislature passed no bill making that transfer, and accordingly the same provisions are now sought to be re enacted. The mistake has been made, however, of not attaching them to the penal code. To enact the bill in its present shape would be to destroy partially the wise principle upon which the Public Health Law was framed and to establish a bad precedent for future legislation."

A law was passed providing that any medical society now organized in any of the counties of the State set apart since the passage of the act of 1813 to incorporate medical societies for the purpose of regulating the practice of physic and surgery in this State, shall, upon complying with the provisions of this act, enjoy the same privileges and possess the same powers as the societies incorporated by virtue of said act now enjoy and possess, but subject, nevertheless, to the provision of any acts or parts of acts heretofore passed in relation to medical societies or to regulate the practice of physic and surgery in this State. Before any such society shall be entitled to the privileges and possess the powers as provided in this act, such society, at a regular meeting thereof or at a special meeting called for that purpose, after due notice to all its members, shall make and file with the Secretary of State a certificate signed and acknowledged by its president and secretary, stating the name of such society, the date of its organization, the name and residence of its members; that the said society, by a majority vote of its members, has elected to become and be a body corporate under and by virtue of said act, and be subject to the provisions of any acts or parts of acts heretofore passed, and now in force, in relation to such societies or the practice of physic and surgery in this State. Upon filing the certificate such society shall become and be a body corporate under the name set forth in said certificate, the same as if such society had been incorporated under and pursuant to the provisions of the said law.

The trustees of Columbia College were made the legal successors of the trustees of the College of Physicians and Surgeons for the executing of all trusts in the city of New York, and the consolidation was legalized. The same city was authorized to expend $200,000 for additional buildings for the Gouverneur Hospital. The Governor vetoed a bill changing the name and increasing the powers of the trustees of the West Side German Dispensary. The city is to pay 38 cents a day for each infant cared for in the babies' ward of the Post Graduate Hospital, and $15 for each mother in the Mothers and Babies' Hospital. The Hahnemann Hospital, the St. Mark's Hospital, and the Manhattan Hospital Association were released from certain assessments. A charter was granted to the Rochester Homœopathic Hospital. The law of 1889, relative to the formation of hospital corporations, was amended so that certificates must be passed upon by the courts. The Governor vetoed and afterward signed a bill for the relief of the Goshen Sanitarium Company, of Goshen. He vetoed a bill forbidding autopsies in insane asylums or hospitals unless the authorities of the county from which the deceased came had been previously notified. An appropriation was made for a homœopathic insane hospital on the Collins farm in Erie County. A bill failed to pass providing that in all hospitals or asylums homœopathic physicians shall be appointed equally with physicians of the regular school.

None of the amendments to the pharmacy laws were successful. One of these provided for a yearly license fee of $1. Another allowed an applicant to secure an order for a license from the court if not entitled to the same within three months after the organization of the board. The Governor vetoed amendments to Sections 184 and 187 of the Public Health Law so as to enable persons who have failed to apply for their licenses as pharmacists within the time prescribed to make application hereafter, and also to correct a clerical error in the existing section by changing the word "resignation" to "registration." The only amendment made to Section 187 was to correct the spelling of the word "peppermint," and another clerical error was made in the bill by changing the word "usual" to "unusual," so as to permit the sale of unusual domestic remedies by retail druggists in the rural districts without license as pharmacists and to prohibit the sale by them of usual remedies. The Governor stated in his veto that the new clerical error was worse than the old one.

A bill paying $3,000 a year to the physician to the coroner of Kings County for autopsies was vetoed. Bills did not pass: Providing that $15 shall be paid for autopsies ordered by coroners; giving a salary of $3,000 to each of the two coroners in Erie County; providing for the appointment of a State dental instructor; amending the Public Health Law so that a diploma may be given to anyone who had been practising dentistry for six years previous to June 20, 1879; amending the same law so as to make examinations for veterinary practice more stringent, and providing fines for violation of the same; extending to January 1, 1895, the time for registry of veterinarians who have no diploma from a college or society; and exempting veterinarians from jury duty. A State veterinary college was established at Cornell University, and $50,000 was appropriated for the same.

An amendment to the charter of the New York Society for the Relief of Widows and Orphans of Medical Men was passed, stating that the objects of said society are benevolent, and to afford relief to the widows, orphans, and dependent relatives of medical men. An amendment to the code of civil procedure requires an examination by a female physician or surgeon in cases where a female must be examined physically. The pay of police-force surgeons in New York City was increased from $2,250 to $3,000 a year, and the act was made to apply to Brooklyn also. A fine of $100 was ordered for every omission in reporting deaths, births, and marriages in New York City. A bill failed to reach the Governor providing that it shall be the duty of the State Board of

Health to make an analysis of all patent medicines and charge a fee of $50, and providing that patent medicines shall not be sold unless examined and approved by the State Board. The Governor vetoed a bill prohibiting the giving away or selling after October 1st, next, of any poison or poisonous substances in liquid form except in fluted bottles labelled in the manner heretofore provided by law. In his veto the Governor said: "The questions at once suggest themselves what is meant by 'poison or poisonous substances,' why the act should be limited to poisons in liquid form, and what is meant by 'fluted' bottles. A measure of this kind might be of service, but it should be more carefully worded so that it would not require a decision of the courts immediately to determine what it meant. A fluted bottle may be any one of a dozen or more different styles. Poisons and poisonous substances are very indefinite words."

Syphilis as a Ground for Divorce.—The Supreme Court of Vermont considers, in the recently decided case of Ryder *vs.* Ryder, syphilis as a ground for divorce. There is in that State, as in many of the other States, a law which provides that the marriage contract may be annulled when at the time of the marriage either party was physically incapable of entering into the marriage state. It was found in this case that the wife, from whom the husband asked to be divorced, had, at the time of marriage, chronic syphilis, which was incurable; that at the time the man who married her supposed her to be chaste; that in about two months she communicated the disease to him; that he did not know that she had the disease until she communicated it to him; that he voluntarily cohabited with her before and after he knew of her disease; that a child was born to them about a year and four months after their marriage; that the child was a mass of syphilitic sores, attributable to the condition of the mother, and soon died; that, at the birth of the child and afterward, the mother was in about the condition of the child from such sores; that they both consulted a physician, who treated them some time, when she got better; that he believed from that time, until the child was born, she had got well of the disease, and would not be troubled again with it; that he never had intercourse with her after the birth of the child; and that at no time could he have sexual intercourse with her without great danger of contracting the disease. Upon these facts, the question presented to the Supreme Court was whether the trial court was in error in refusing to annul the marriage A majority of the court thought it was. It was not found that the woman was fully aware of her condition at the time of the marriage. It would be presumed that she was not. If it were found that she was fully aware of her condition, she would have been guilty of a fraudulent concealment in not disclosing it to him she was about to marry. It would be an essential fact, entirely within her knowledge, not within his, nor open to his observation nor to his inquiry upon any reasonable principles which do or should prevail in conducting the negotiations which lead up to entering into the contract of marriage.—*Cincinnati Lancet and Clinic.*

The Last Illness of Dr. Brown Séquard.—Dr. Ogle gives in *The Lancet* an interesting account of the illness of the late Dr. Brown-Séquard. It appears, he says, that for some years past Dr. Brown-Séquard had not seemed to his friends to be in good general health. He had, in 1889, been the subject of severe muscular rheumatism, and in the autumn of that year he suffered from some prostatic trouble. From these ailments he entirely recovered. During the following winter and spring, when at Nice, he had an attack of whooping-cough, as was mentioned in *The Lancet* at the time. He was then regularly using his orchitic fluid injections. During the next two years he remained fairly well, working very hard and writing much, sometimes answering as many as eighty letters in the day. In the summer of 1893 he suffered great distress of mind owing to the ill-health of his wife, and in December he was residing at Nice and was confined to his bed, suffering from phlebitis, when his wife was dying. The consequent grief perfectly unmanned him, and was quite uncontrollable, and for some time he took but little food and was unable to sleep, refusing to leave the house. He returned to Paris at the beginning of March. Then came the vertigo and affection of sight, followed by the unconsciousness which he himself wrote about to Dr. Waterhouse, and from which he recovered. Dr. Dupuy says that at that period the speech remained "thick" and embarrassed at times, and that Dr. Brown-Séquard remarked: "This is an attack of epilepsy, as you can see." Instead of going to bed as desired, he wrote several letters, and, no doubt, wrote the letter to Dr. Waterhouse above alluded to, relating his symptoms and speculating upon them. During the following day he was in the same condition as regards vertigo, hemiopia, and occasional thickness of speech, but there was no aphasia. He was then visited also by his friends, Dr. Dejévine and Professor Potain, together with Dr. Dupuy, but could not be persuaded to take adequate rest and nourishment. On the next day (Friday) he consented to take meat, milk, and bread in small quantities throughout the day, and was comparatively cheerful. At the close of the day his face became much flushed, and the vertigo and hemiopia very distressing, and in consequence of this he walked from one room to another on "all fours," giving at the time the analysis of his symptoms and the prognosis of his case, as if he was contemplating and discoursing on the illness of another person. During the night of that day he was seized with vomiting, and in the early morning it was found that he was unable to speak and that the left arm was paralyzed as to power of movement. Dr. Dupuy found later on that paralysis of the muscles on the right side of the face existed and that the tongue was protruded to the right side. The left leg and the arm and leg on the right side were unaffected. There was no muscular spasm in any part, no interference with sensation, either general or special; but vertigo was much increased, and there was external strabismus of the right eye. The condition of speech was the same, and there was still no aphasia. Toward the evening of the day the face became exceedingly congested on several occasions, and the blood vessels of the forehead much swollen, and there was drooping of the upper eyelid of the right eye. During the morning of the next day (Saturday) he made Dr. Dupuy understand that he wished to write on a slate, but the result was unintelligible, excepting that the word "hyperæsthesia" was recognized. He then saw some friends with pleasure. At 2 A M on Sunday he became entirely unconscious, and coma set in. The axillary temperature rose to 40° C —*i.e.*, 104° F., and he died without a struggle near midnight. After the cessation of breathing and of the heart's action all the muscles of the legs and arms were for several minutes in a state of fibrillary contraction, and the axillary temperature at the point of death rose to 41.5° C.—*i.e.*, 105 9° F. No post-mortem examination could be made.

Prevention of Iodism —Dr. H. N. Spencer (*Int. Med. Mag.*, December, 1893), recommends the following mode, due to Professor Hardaway, of prescribing iodide of potassium; the tendency to coryza is counteracted by the nux vomica and ammonio citrate, while the tonics prevent depression:

℞ Iodide of potassium ..... ℥ ss.
Citrate of iron,
Ammonium ..... āā ʒ j.
Tincture of nux vomica ..... ♏ ij.
Water ..... ℥ jss.
Compound tincture of cinchona to make up ℥ iv.

Dose, one teaspoonful in half a glass of water after meals. The quantity of iodide may be increased to any desired extent by adding the necessary amount of a saturated solution.

Insanity is Increasing in Ireland, according to a recent parliamentary report.

The Fee for Medical Witnesses in the London police courts is half a guinea, or about $2.50.

TEN YEARS' EXPERIENCE WITH ALEXANDER'S OPERATION FOR SHORTENING THE ROUND LIGAMENTS OF THE UTERUS.

SIXTY-FIVE OPERATIONS.

BY PAUL F. MUNDÉ, M.D.,

NEW YORK,

PROFESSOR OF GYNECOLOGY AT THE NEW YORK POLYCLINIC AND AT DARTMOUTH COLLEGE; GYNECOLOGIST TO MOUNT SINAI HOSPITAL; CONSULTING GYNECOLOGIST IN ST. ELIZABETH AND THE ITALIAN HOSPITALS.

SOON after the publication of Alexander's little book on the operation revived, and, I believe, first actually performed by him, I, on December 12, 1884, undertook it successfully, following closely the directions laid down in Alexander's work. I was so much impressed with the ease of performance and the immediate and subsequent results of the operation that, during the next two years, I had six cases to report, in four of which I succeeded in finding the ligaments, in drawing them out, and attaching them as recommended by Alexander. My experience with the operation increased so rapidly that in the *American Journal of Obstetrics* for October, 1888, I was able to report twenty-three cases, with but three failures to find the ligaments, and with practically no failure in the other twenty cases as regards the permanency of the result of retaining the replaced uterus in the normal position. In that article I reviewed at some length the indications, results, and technique of the operation, and concluded by raising my voice very forcibly in its favor as against the later, more dangerous, less logical, and permanently less successful operations of shortening of the round ligaments through the opened abdominal cavity, or ventral fixation of the fundus uteri.

That article was not read before any medical society, but was simply printed in the above named journal, where, of course, it was seen by very many members of the profession, but perhaps did not attract as much attention as if it had been more widely circulated through the columns of the weekly medical press, or through the "Transactions" of the medical society before which it might have been read. Hence I am afraid that its precepts and deductions were not so generally appreciated as they should have been. Of course, I can speak only for myself and my own experience, and cannot expect that my professional brethren will unhesitatingly accept and follow my conclusions. But as I am known to be a conservative operator, not only in cœliotomy for diseased ovaries and tubes, but also as regards other operations which may possibly be avoided, I felt that I was entitled, with all due modesty, to more confidence and belief than if the operative furor had had exclusive possession of me. Nevertheless, I am constantly meeting gentlemen who, with quite as much experience as my own in all sorts of gynecological operations, still express a want of reliance in Alexander's operation and a preference for abdominal section with intra-abdominal shortening of the round ligaments, or ventral fixation, for the very same objects for which I unhesitatingly prefer Alexander's operation. It seems very difficult to convince some men that pelvic diseases in the female can be treated otherwise than by opening the abdominal cavity, and that, after all, in very many cases, this should be the last resort, when all other possible means have been exhausted.

Some of these gentlemen base their objections to Alexander's operation on the difficulty of finding the ligaments or the impossibility of drawing them out; others, again, contend that the results of the operation are not permanent; and others, again, claim that cœliotomy is a so much easier and equally safe way of attaining the same object. It is scarcely necessary for me to say that I am perfectly familiar, from a theoretical and practical experience in gynecology of over twenty five years, with the various methods which are preferred to Alexander's operation by the gentlemen to whom I refer. I do not prefer Alexander's operation because I have a particular hobby in its direction, or because I have anything other to gain by my preference than supporting what I think to be best. I can simply point to an experience which has now amounted to sixty-five operations, and which, with the increased knowledge of years, still leaves me a more and more confirmed supporter of the operation.

For minute details as regards the technique and the indications, I will refer my readers to the article published in the October, 1888, number of the *Journal of Obstetrics*. I will add but a few brief remarks as to what is stated there. First, as regards the technique of the operation I will repeat that if the ligaments are not found it is always the fault of the operator. It is simply a question of careful attention to the anatomical landmarks, namely, the spine of the pubis and the external inguinal ring, upon which depends the finding of the ligaments. If the tissues are quickly divided down to the fascia covering the external inguinal ring, this is lightly pricked with the scalpel, the knuckle of fat which pops out through the opening is carefully dissected out bluntly with the handle of the scalpel, always being careful to avoid detaching the bundle of fat from the spine of the pubis; if then this bundle of fat is entirely lifted up from the subjacent bone with mouse tooth forceps or an aneurism needle, a slow, minute, and blunt separation of the tissues thus lifted up will always succeed in revealing the initial fibres of the round ligament, which usually lie at the lower surface of the bundle thus lifted up, and run slightly outward and downward, not entirely outward. If traction upon the supposed fibres of the ligament shows that it runs toward the anterior superior spinous process of the ilium, the operator may be sure that he has picked up fibres of the external pillar of the ring or of the oblique fascia. Careful isolation of these fibres, gentle traction upon them if they prove to run in the right direction, and dull separation of the strand if it appears attached in the canal, will usually in a few minutes enable the operator to draw out the ligament so that its identity is at once apparent both to him and the spectators. This point having been reached, it is merely a question of gentle, continued traction to draw out as much of the ligament as is allowable, that is to say, until its increasing size, usually almost to that of a lead pencil, shows that its attachment to the uterus is approaching. If traction is too severe and too rapid, or if the ligament is either thin or much adherent, it may easily be broken, particularly in its lower two-thirds, and may then be lost to future research, or, if found again, will have to be picked up within the depth of the canal. I confess that I still have the impression, which I had years ago, that this operation requires all the wit and dexterity of the operator in order that by some oversight or carelessness

the ligament may not be lost, broken off, or pushed aside and thus lost.

The one unvarying landmark is always the spine of the pubis, where I have repeatedly succeeded in picking up the ligament, which at first I had failed to isolate in the bunch of fat lifted up according to direction. By non-attention to this landmark the operator may get to one side and manage to pick up some other cord, even drawing it out to a small extent, as in one case operated on by one of my house surgeons, until I, coming to the rescue, satisfied myself and him that it was the femoral artery, which of course was very hastily dropped, fortunately with no evil results. By returning to the spine of the pubis and proceeding thence forward, I in a moment, picked up the terminal fibres of the round ligament, isolated them, and drew out the ligament.

There will always be in this operation one drawback, and that is the possibility that the thinness of the ligaments, their very diffuse attachment to the spine of the pubis, and their uncertain appearance in the suprapubic fat, further, the adhesion of such a thin ligament in the Nuckian canal, may result in failure, either through the inability of the operator to isolate them or in their breaking during his attempt to draw them out. In my last case the ligament on the left side appeared to be unusually friable, for it broke close to its uterine origin, the only instance where I have seen it torn so high up. By passing the first suture very deeply I managed, however, to keep the left horn of the uterus close to the anterior abdominal wall and the result was perfect. This accident, the breaking of the ligaments, is, in my experience, the only drawback which this operation possesses. And I think by extreme care in traction it also can often be avoided.

I always stitch as much of the ligament as is not drawn entirely out of the external inguinal ring into the canal by passing a number of silkworm-gut sutures through each pillar of the ring and the ligament between, cutting off the supra abundant portion of the ligament. I have very seldom found it necessary to split up the inguinal canal to the internal ring to find the ligament, and then only when the ligament had been torn off during my first attempts at traction. I can see no use in opening the whole inguinal canal at first to perform the operation. It strikes me like a confession of timidity at the very outset to see this done. I am sure that out of the sixty five cases which I have performed I have not been obliged to open the whole inguinal canal in more than half a dozen cases. The usual length of my incision is not more than two inches.

Suppuration has occasionally resulted, particularly if much tearing and manipulation was required to find and draw out the ligaments. I formerly employed a split bone drainage-tube, but have for some years entirely discarded it, and cannot say that my cases have done any worse. Even if suppuration did take place in the wounds, the adhesion of the internal end of the ligament seemed to be quite firm enough to keep the uterus in position.

None of my patients have ever shown the least dangerous symptoms in consequence of the operation, although several times convalescence was prolonged to four and six weeks in consequence of suppuration. Never have I seen an inguinal hernia follow the operation. On the other hand, I have cured an inguinal hernia by the operation. I have always introduced a pessary into the vagina immediately after the operation, in order to prevent undue strain upon the newly attached ligaments, and have had it worn for from three to six months. Of course if perineorrhaphy was done at the same sitting a pessary could not be used.

As regards the length of time required to perform Alexander's operation, I would say that much depends upon the character of the case. In an easy case without adhesions I have frequently succeeded in completely drawing out both ligaments in from five to ten minutes for each side. The stitching, of course, must be carefully done, and the whole duration of the operation will probably not be less than thirty minutes. I need scarcely say that it is always imperative to draw out both ligaments, since to shorten only one ligament would result in placing the uterus in an oblique position.

Second. As regards the indications for the operation I would say that I consider the lines very closely drawn. Only a sharply retroverted or retroflexed uterus, with more or less descensus, with more or less relaxed vaginal walls, with perfect mobility of the uterus and adnexa, justifies Alexander's operation. I say justifies, but I do not necessarily mean that these conditions are an absolute indication for the operation, since in many such cases perfect relief may be given the woman by a properly adjusted pessary. It is only when a pessary cannot be fitted or comfortably worn, which will retain the uterus and ovaries in their normal position, or when the patient insists upon being cured instead of being merely temporarily relieved by a pessary, that we can say that Alexander's operation is indicated.

Whenever the uterus or appendages are adherent, Alexander's operation is absolutely and positively contra-indicated. We can, therefore, not compare the indications for Alexander's operation and those for ventral fixation, in my opinion, since the latter is justified and indicated only when adherence of the appendages or of the uterus warrant our opening the abdominal cavity and detaching the adhesions. Then, of course, it is scarcely worth while to do an Alexander's, since it adds very little to the danger to sew the uterus to the anterior abdominal wall. In such cases of adherent uterus and appendages, however, where they have been detached through an abdominal incision, the operation of shortening the round ligaments by doubling them upon themselves, as recommended by Wylie, A. P. Dudley, Mann, and others, should be considered. I have but one experience with this operation, which is still too recent to enable me to offer a positive opinion on the subject. Technically it is exceedingly pretty, logical, and easily effected. In prolapsus uteri I am not in favor of Alexander's operation, except in so far as it is one in a series of operative measures by which a retention of the uterus in its normal position in the pelvis is to be attained. Alone, Alexander's operation is, in my opinion, of no permanent benefit for prolapsus uteri. Neither do I consider it applicable to cases of anteversion and anteflexion in which it is thought advisable to lift up or straighten out the fundus uteri by drawing it up. In prolapsus uteri my experience is that the round ligaments are not able to withstand the constant downward strain upon them of the large body of the uterus. In anteversion and anteflexion the direction of elevation of the fundus produced by shortening the round ligaments would be such as to drag the fundus against the symphysis pubis and produce uncomfortable pressure on the bladder.

Third. In a very large proportion of cases where Alexander's operation is indicated, there exists, besides the retroversion and retroflexion and descensus of the uterus, a want of tone or an absence of the inferior uterine and vaginal supports, namely, the perineum is lacerated, the bladder and anterior vaginal wall and the rectum and posterior vaginal wall are prolapsed. While we can very easily lift up, and even retain in position, the backward displaced uterus and appendages by Alexander's operation, it stands to reason that a permanency of the result will be more assured by restoring to their normal conditions the inferior supports of the uterus and vagina; and often also a laceration of the cervix exists at the same time which maintains a chronic enlargement of the uterus. I therefore always combine with the Alexander's the restoration of these various organs, so far as possible, to their normal conditions. Thus if there is a laceration of the cervix, a retroflexion with descensus, a lacerated perineum, a cystocele, and a rectocele, I proceed in the following order: 1st, trachelorrhaphy; 2d, Alexander's; 3d, cystocele, Stoltz's operation (if still necessary after the uterus is replaced); 4th, rectocele with perineorrhaphy (Hegar's operation); or, if there be no rectocele

but simply a lacerated perineum, I restore the perineum by the flap-splitting method. I have frequently been able to perform this series of operations in less than an hour and a half, and I have yet to regret having done so, both as regards the immediate result on the patient (long duration of anæsthesia, loss of blood) and permanent results.

Fourth. After the technique and indications of the operation naturally comes the question as to its results, that is to say, does the uterus which has been successfully placed in its normal position by the shortening and attachment of the round ligaments to the inguinal canal remain in that position for the rest of the woman's life, in spite of the daily influences which tend to again displace it, and particularly in spite of the occurrence of pregnancy and parturition? This question would be an exceedingly easy one to answer if we were able to retain all, or even the majority, of our patients under observation. Manifestly this cannot be the case, since even in private practice comparatively few operative cases again present themselves, especially not if they are doing well. It is usually only those in whom the condition for which they were treated returns from whom we hear in an unpleasant sense, either personally or through friends. Comparatively few show their sense of gratitude by presenting themselves for the purpose of giving us the satisfaction of seeing how well we have succeeded; hence I can only refer to a certain number of my sixty-five cases of this operation in support of my statement that the operation has been a permanent success. Still the old saying, that "Straws show which way the wind blows," may possibly be applied to this operation. I can but say that of all those women upon whom I have operated during the last ten years for shortening the round ligaments, but two have come under my personal observation in whom the operation eventually proved a failure. In one of these the operation was performed for prolapsus uteri, the uterus being very large and heavy, a case in which I now consider the operation contra-indicated. In the second, the ligaments had been torn during their attempted extraction, and primarily the operation must be considered to have been at least a partial failure. I must add to these two cases three others in which, in my earlier days, I failed to find the ligaments; here the want of success must not be attributed to the operation, but to the operator. As regards the permanency of the success, I have had the opportunity to examine probably about one-half of my cases for a period varying from six months to as many years after the operation, and in none of them, I can honestly say, have I found the uterus to have deviated one iota from the position in which I put it. At the time of my last article, six years ago, I had not had the opportunity to see any of my cases undergo the crucial test of pregnancy and parturition; but since then not only have Drs. Coe and Boldt reported to me, if I remember right, each two cases, and Dr. Henry S. Stark one instance of that occurrence which had come under their observation, in which the uterus retained after confinement the normal anteverted position; but I myself have seen four such, in one of which I saw the patient in consultation for puerperal septicæmia in her fifth confinement, the other also for puerperal septicæmia in her first confinement, six years after the operation, and in all these cases the position of the uterus was absolutely normal. I do not suppose that it is necessary to say that the septicæmia in these cases had nothing to do with the Alexander's operation, but was merely accidental. Some of my operations performed during the last six months are of course too recent to enable me to draw conclusions as to their permanency. I would say that during the past eighteen months I performed twenty-one Alexander's operations, every one successfully.

In conclusion, while I do not undervalue the difficulties of the operation, and the uncertainties which will always be attached to it, I still must assert my unqualified belief in it, in properly selected cases, in preference to the other dangerous, and, as regards permanent results, no more certain, operations of ventral fixation and intra-peritoneal shortening of the ligaments.

A CASE OF CASTRATION FOR PRIMARY TUBERCULAR EPIDIDYMITIS IN A PATIENT AGED EIGHTY ONE.[1]

By C. L. GIBSON, M.D.,

NEW YORK.

ATTENDING SURGEON ST. LUKE'S HOSPITAL; ASSISTANT SURGEON ST. MARY'S FREE HOSPITAL FOR CHILDREN.

It is with a certain misgiving that I offer to your attention the description of a single case, presenting neither an extraordinary rarity nor novelty of treatment.

The subject of genito urinary tuberculosis, especially of the testicle, presents many points of interest in the way of frequency, etiology, pathology, exact diagnosis, prognosis, and treatment. Every one of these points has been and is the subject of widely varying opinions. The literature is simply terrifying. A glance at the pages in the "Index Catalogue of the Surgeon-General's Library," on the article "Tubercular Testicle," led me to think it highly presumptuous on my part to try to add to this wealth of material. And yet it is most disappointing to find how often this material fails to enlighten us on any one particular point on which we seek information. Perhaps it is still more astonishing that a work bearing the promising title "The American Text Book of Surgery" should dismiss the consideration of tubercular testis in exactly nineteen lines.

The subject of this paper does not pretend to settle the many disputed points. I wish to emphasize some of the facts of this case as a possible support for the radical treatment of tubercular testicle, which I favor, although in a general way I am ready to fall into line with the present moderate plan of treatment of surgical tuberculosis in general, which has followed as a healthy reaction against the furor of attempted radical measures of the previous decade.

The following is a résumé of the case as furnished by the hospital records:

Henry W——, eighty-one years of age, born in Newfoundland, formerly a nurse, was admitted to St. Luke's Hospital, New York, August 13, 1891; service of Dr. F. H. Markoe, Attending Surgeon. To his great kindness I am indebted for the opportunity of treating and reporting the case.

Family history: Good.

Previous history: No rheumatic, malarial, cardiac, pulmonary, or renal history. No previous disorder of the genito urinary organs, save a single attack of gonorrhœa forty to fifty years ago. Double reducible inguinal hernia for fifty years.

Present history: Nine days previous to admission, while carrying a man down-stairs, he stumbled, sustaining a strain referred to left groin. In a day or two the left testicle became swollen and there was tenderness running up into the abdomen. (He thinks the organ has always been a little the larger.) The symptoms described increasing, he sought relief in hospital treatment.

Examination: The left half of the scrotum is occupied by a globular mass, diameter three inches, tense, elastic. At the upper and posterior portion the thickened and hardened epididymis can be made out. The cord is somewhat thickened, but smooth. Tumor translucent. Examination per rectum negative. No urethral discharge. Double reducible inguinal hernia. Pigmented scars on both legs.

On admission the temperature was 98° F.; pulse, 84; respiration, 20. Urine: Acid, clear, specific gravity 1.020, two per cent. albumin; no glucose. Microscopically a few red blood-cells and leucocytes.

Treatment: Regular diet, salts, suspensory bandage,

[1] Read at the meeting of the Harvard Medical Society of New York, January 27, 1894. The patient was also presented at this meeting.

and counter-irritation by Paquelin cautery. The next day it was noted that he was comfortable.

August 18th.—Pain continues. Ordered ung. hydrarg. locally daily.

August 26th —Condition unchanged, explored with hypodermic needle, clear fluid. Stop ung. hydrarg. Resume cautery.

August 28th.—Fluid about an ounce and a half entirely evacuated, giving considerable relief.

August 31st.—Swelling has returned, with further evidences of inflammation.

The diagnosis of a tubercular epididymitis had been established for some time. The increasing acuteness of the symptoms seemed to indicate operative interference, which was accepted by the patient. Accordingly, September 1st, the preparations for thoroughly cleansing the skin of the operative field were begun. Examination of the chest showed heart sounds distant and feeble. Lungs emphysematous, urine (previous to operation) acid, clear, sp. gr. 1.016, one per cent. albumin, many leucocysts and epithelium, hyaline casts.

September 4th.—I operated, having the kind assistance of Dr. Markoe. Previous to etherization atrop. sulph. gr. $\frac{1}{100}$, and whiskey 3 vj., were given. An incision one and one-half inch long, subsequently enlarged to two inches, from a point over body of pubes downward. Spermatic cord isolated, apparently normal. It was transfixed and tied high up with catgut ligatures, and divided. Constituents of cord isolated, and five fine catgut ligatures applied. Coverings of testicle separated and organ turned out, during which purulent contents escaped into the wound to a very slight extent. About one-third of scrotum ablated with testicle. Moderate hemorrhage. Union by mattrass and continuous suture of catgut. No drainage. Sterilized dressing over protective tissue.

Ether was very well borne; no nausea followed. There was considerable depression in the first few days. Stimulating food was diligently given, and he was gotten out of bed into a steamer chair in two days; this I think doing much to prevent him from getting into that hopeless state of apathy when old people are confined to bed. Five days after operation the dressing had to be inspected, as it got disturbed by moving him about daily. There was primary aseptic union. A second dressing for protection reapplied. He gradually regained his strength; for several days his mind was pretty feeble, but he was able to leave the hospital eleven days after the operation in pretty good shape.

The testicle removed was thus reported on by the pathologist, Dr. J. S. Thacher: "Microscopical examination shows typical tubercular changes. There are a large number of giant-cells, many tubercles, some tubercle tissue, and a little cheesy degeneration." There is no record of the microscopic changes. Six months ago, two years after the operation, I saw the patient again. He was waiting in my office for me one very hot day, feeling very comfortable indeed, while I was absolutely done up. Of the two he seemed by far the most vigorous. The scar was almost imperceptible, and save some disturbances of vision he was absolutely free from evidences of disease of any kind. His mental condition was as clear and vigorous as you could expect of a man aged eighty three.

This result of this case is exceedingly gratifying and has some points of interest. I think there are not a few surgeons, even to-day, who would have refused this elderly patient the radical operation of castration. Certainly the majority of practitioners, unfamiliar with the actual possibilities of thorough modern surgery, would not have suggested it to the patient. There is a good deal of superstitious horror still prevalent about the dangers of castration; sepsis, prolonged suppuration, secondary hemorrhage do not or should not exist, and these formerly made the operation hazardous. In this case we realized that the operation must be speedy and the convalescence smooth. The elaborate preparations of the skin prior to the operation sought to overcome one of the most frequent causes of wound suppuration, and rendered unnecessary any half-hearted and inefficient cleansing on the operating-table, which adds to the time. The operation was done quickly, and with scrupulous regard for the details of surgical cleanliness. The close approximation of the divided tissues made drainage unnecessary, obviating frequent change of dressings and pain and leaving no indolent sinus. The administration of atropine before the operation gave a certain protection against exhausting nausea after etherization. The immediate operative shock was not marked. I have already pointed out, in a paper in the *Annals of Surgery* for October, 1893, that the occurrence of shock in operations in advanced age is more theoretical than real.

The result in this case seems to point to the occurrence and radical cure of a primary tubercular epididymitis by castration. This statement at once brings us into a controversy as to the pathology and consequent indications. There is the older view that a tuberculosis of the genito-urinary system is only a part of the evidence of a general constitutional infection. This is true only to a certain extent.

Admitting, then, that there is a genito urinary tuberculosis while the remainder of the body is free, there are two views, the one, strongly upheld among others by Guyon, that a tuberculosis of the epididymis is never localized to it, but is accompanied by, or secondary to, some other tuberculosis of the genito-urinary system, notably the seminal vesicles. On the other hand there is the view, supported by one of the latest and best works, Jacobson's "Diseases of the Male Organs of Generation," that the epididymis is usually the first seat of the affection.

The figures indicating the relative frequency of phthisis in connection with tubercular testis are hard to estimate. In a series of 102 cases, of Terrillon and Reclus, of tubercular epididymitis, 57 cases also had phthisis. Reclus's thesis of 1876 found that only one case in three had phthisis; the same ratio is given by Wilson. Again, from the observations in the Pathological Institute at Prague we find that in 1,317 cases of phthisis the testicle was involved in the tubercular process only thirty-seven times.

Guyon denies the existence of a localized tubercular epididymitis. In 26 cases of autopsies of the genito-urinary tract the occurrence of foci confined to the epididymis was never observed. His observations of 222 cases of genito-urinary tuberculosis showed the following relations:

Forty cases of isolated genital tuberculosis; 74 cases of genito-urinary tuberculosis; 108 cases of combined genito-urinary tuberculosis. Now if it were true that tubercular epididymitis never occurs except as part of a diathesis or as part of a tuberculosis of the genital or genito-urinary system, the indications for castration would be pretty limited.

The evidence both of everyday clinical observation and the statistics quoted above, and, finally, the case under consideration, show that a genital tuberculosis may exist independent of phthisis. At once the indications for operation increase. Guyon's statistics are those of a specialist who sees the late case when a tubercular process has spread. Early radical treatment would much lessen the gloomy statistics of such specialists. For it is evident that removal of a diseased testicle, if complicated, we will say, with disease of the seminal vesicle, would only be a palliative operation with very narrow indications. The truth of the matter is, we do not accurately know just how the process develops. It seems apparent that in some cases it must develop primarily in the epididymis, the seminal vesicle being secondarily involved, and vice versa. My personal feeling is that the view which always makes the seminal vesicle the source of infection of the epididymis cannot be true; certainly not in the case under consideration (I take it for granted that the epididymis is attacked before the testicle, which, however, is almost invariably attacked with the progress of the disease). If it were possible to establish what

part of the epididymis is first attacked, some light might be obtained on the subject, although Mr. Jacobson says, "this is a point which has been much and needlessly discussed." In the majority of cases the first evidence of disease is found in the head of the epididymis where the spermatic artery breaks up and one branch enters the epididymis. The vessels of the epididymis are smaller and more tortuous than those of the testicle or vas deferens. This would point to infection from the blood-supply and show the priority of the process in the epididymis and not the seminal vesicle. The tendency of tubercular processes to become localized where the condition of blood-supply is most abundant and complex is well known, especially in the epiphyses, while on the other hand in tuberculosis of the tendon sheaths the poorly vascularized tendons remain unaffected although buried in tubercular tissue. I think on the whole we can accept this theory of infection by the blood supply to show that the process is primary to the epididymis and therefore admits of conditions favorable to operative relief. The question of infection from coitus, and consequently of the epididymis secondarily to infection of the seminal vesicle, has but little to support it, and is in the main fanciful. Mr. Jacobson says that if the theory were true, tubercular disease of the sexual organs should be more common than it is. That tubercular testis is at times congenital, that it follows upon injury as in our case, certainly are decided arguments against the coitus theory.

What guides have we in general for the treatment of tubercular testis? We have to consider the classes of cases and the classes of treatment available. I propose the following divisions:

1. Tuberculosis of the testicle (or epididymis or both), all other tubercular lesions being wanting. 2. Tuberculosis of the testicle and other portions of the genito-urinary tract. 3. Tuberculosis of the testicle and chronic pulmonary tuberculosis. 4. Tuberculosis of the testicle and other portions of the genito-urinary tract and chronic pulmonary tuberculosis. 5. Tuberculosis of the testicle forming part of a general acute miliary tuberculosis.

To combat these conditions we have at our disposal: 1. General constitutional treatment—hygienic, dietetic, climatic, and medicinal. 2. Palliative measures—evacuation of pus, curetting, caustics, thermo-cautery, resection, castration. 3. Radical measure—castration.

In all forms of the disease, save the rapidly fatal cases of acute miliary tuberculosis, the general constitutional treatment should be pushed to the fullest extent possible. It puts the patient into the best possible condition for repair of damage and checking of further invasion. To specify fully a judicious course of treatment would be to write a good-sized work. That constitutional treatment *per se* is curative, forever stamping out the disease, I do not admit—many early cases are apparently cured, many severe processes are temporarily ameliorated. A tubercular focus in any part of the body is likely to light up again at any time, although remaining dormant for years. The literature gives many such cases. The favorable absolute reports that have been quoted from time to time, to support the curative effects of constitutional treatment, either are issued too early or admit of doubt as to exact diagnosis.

I have said before, it is indicated in every one of the five phases just described. Are there any forms in which it becomes the only treatment? How far it will be employed in the fifth form is a matter of expediency. In the first form it will play a secondary part, the chief factor of success being early and radical removal of the primary focus.

In the next three forms it comes to the front, as here the operative measures can only be palliative; but in none of them is the possibility of improving the patient's condition by interference excluded, though the benefits grow less with the increasing complexity of the lesions.

We come now to the application of the palliative method. One of these methods, resection of diseased nodules in the epididymis, is quasi-radical, but presents no particular advantage, as it will scarcely maintain the function of the gland intact, and, being probably incomplete, is a waste of time when delay is dangerous.

The other varieties, incision of abscesses, use of sharp spoon, packing with iodoform gauze, cauterizing with chloride of zinc, burning with thermo-cautery, can never be indicated in Class 1, of localized primary tuberculosis of testis or epididymis. The remaining three forms may all be benefited but not cured by this means of treatment. (Strictly speaking, Class 3, localized tubercular epididymitis with phthisis, might be included with Class 1, although tubercular disease would not be banished from the body by an operation.) How far minor palliative measures, properly speaking, are to be preferred to castration, even as a palliative measure, will be discussed in the consideration of that operation.

We come now to the application of castration. In Class 1, where our diagnosis is absolutely trustworthy as to the limitations of the disease, and we can put the patient in a condition to withstand or avoid new formation of tubercular deposits, the result will be exceedingly gratifying. There are many cases of total cures persisting for many years which are on record to bear out that statement.

Great care must be taken, though, to assure ourselves that we are actually dealing with a localized process. If we grasp the spermatic cord above the tumor, and find that it is entirely free from enlargement and localized swelling and painless, we have not yet assured ourselves as to the condition. A most careful examination of the seminal vesicle per rectum is necessary; this requires considerable knowledge of the normal condition to detect the abnormal in early cases. The seminal vesicle may be recognized as diseased, while the cord appears or is normal. This peculiarity is explained by the usual limitation of the process at one or both of two points, the testicular end just above the tail of the epididymis, and at the distal end where it joins the seminal vesicle.

As to the application of castration in any of the three remaining forms, it seems to me, broadly speaking, to be indicated as a palliative measure in those two forms which I have made of the trouble in the genito-urinary tract. The indications are even more positive in the form of localized testicular trouble complicated by phthisis, provided the patient's general condition warrants doing an operation requiring general anæsthesia. In this case, if the patient can be brought under favorable circumstances, the process in the lungs may and can be arrested for a long time. In any of these conditions, as Mr. Jacobson very judiciously remarks, the patient is relieved from one of his two burdens—tuberculous lungs and suppurating, crippling, perhaps painful testis.

Guyon goes so far as to counsel invariably (within limits of reason, of course) the use of castration as a palliative measure, although he absolutely rejects its use in the early stages before the testicle is materially involved. Believing as he does that the process is conveyed from the seminal vesicle to the epididymis, he rejects the operation as curative, but indorses it most warmly as a palliative measure. After removal of the testis, where there is a genito urinary tuberculosis elsewhere, the relief from the acutely suppurating focus may give the system more vigor to combat the remaining process and possibly retard it.

The presence of a localized suppurating focus was long, and is yet, in some quarters, considered as a *noli me tangere*, for fear that interference with it may cause a general outburst of tubercular trouble. On this point Guyon expresses himself very positively as follows: "The most scrupulous surgeon may in all conscientious security attack a suppurating tubercular focus (provided that indications exist), without the slightest danger of injury to the general system."

That such an outbreak of general symptoms may occasionally arise as a result of localized operative interference, I am not prepared to deny. I have never seen it

occur after any operation for the relief of surgical tuberculosis.

Being relieved of a distressing local complication the patient is better able to go about, to live an outdoor life, to indulge in proper exercise, all of which are so necessary for improvement of the general health. Moreover, he is able to return promptly to work: of great importance to a poor man with a family. In one case I castrated a man for a pretty advanced process, and he resumed work as porter in a wholesale house in ten days.

As opposed to castration are dangers of an operation, apparent loss of virility, and consequently danger of hypochondriasis.

The surgeon must judge in each individual case how much advantage is to be obtained from an operation, how much any given patient can stand. As to the apparent loss of virility, the disappearance of both testicles may produce a marked effect on the mind. Perhaps here amputation of the worst, and mild palliative measures on the other might be indicated. Or, as has recently been most successfully done by Dr. R. F. Weir, a cylinder of celluloid resembling a testicle might be introduced into the scrotum and allowed to become embedded. Certainly, fear of mental changes ought not to deter us from removal of one testicle; it is more likely that a better effect is to be looked for by the removal of an unsightly and disagreeable condition which of itself would naturally be an obstacle to sexual relations.

The more carefully we weigh the results of castration, the little danger of the modern operation properly done, the wider seems to be the field for it. Of the further operation of removing diseased seminal vesicles, although some few brilliant results are beginning to be recorded, it is not within the province of this paper to discuss; the operation being still *sub judice*, and at present offering little in its favor. Of course, if it come to receive general recognition the indications for castration would be markedly increased.

The treatment of tubercular disease by injection of the substance known as Koch's tuberculin, which was recently hailed by the profession with such hysterical enthusiasm, has to day no standing, and need only to be mentioned to be condemned.

As to the sclerogenic method of treatment by injection of chloride of zinc, which is now on trial, I can say nothing in this connection as I am unaware of its employment in the form of disease under consideration.

Just as in malignant disease, early interference must give the best chance of effecting a cure. The responsibility of this rests chiefly on the recognition of the disease and the possibilities of treatment by the general practitioner.

It is to be hoped that our resources of exact diagnosis may be multiplied to allow of treatment of the disease by knowledge of its nature, without waiting to be compelled by urgent symptoms. The bacilli may be recognized sometimes in the fluid of the hydrocele, which occurs in about one-third of the cases. The centrifugal machine may be of use in facilitating the accumulation of solid particles. If there is pus, the bacilli will probably be found readily. Any of these fluids may be used to inoculate suitable culture media. Or the fluid may be used to inoculate animals susceptible to tuberculosis, *e.g.*, guinea-pigs. The semen is occasionally found to contain bacilli; other means failing it might yet afford a clew to the exact nature of the disease. And exactness is what we want to enable us to move early.

From consideration of some of the elements presented by the case reported, the following observations seem justified: That tubercular testis may occur as an idiopathic primary condition; that it may first appear in advanced age; that advanced age is no obstacle to successful interference.

I know that many interesting points have not been alluded to—the present paper has no pretension to exhaust the subject. Though I have made no extensive search on this line, I think that the great age of the patient and the result make the case unique.

THE TRANSMISSION OF THE CHOLERA SPIRILLUM BY THE ALIMENTARY CONTENTS AND INTESTINAL DEJECTA OF THE COMMON HOUSE-FLY.[1]

By THOMAS C. CRAIG, M.D.,

PASSED ASSISTANT SURGEON, U. S. NAVY, NAVY YARD, NEW YORK.

While working with cholera in the Hoagland Laboratory of Bacteriology, it occurred to the writer to undertake a series of experiments to ascertain whether it were possible for the common house fly to carry the cholera spirillum and deposit it in a living state, and thus be one of the factors in the contagion; and also to ascertain whether cholera was fatal to flies within the time necessary for them to carry it to distant parts.

A fresh bouillon culture was made from the stock cultures in the laboratory, originally obtained from cases of cholera at Swinburne Island in 1892. Three large flies were caught and placed in a small wide mouthed bottle. A small piece of bread was then moistened with the beef-tea cholera culture, and put into the bottle along with the flies. They eagerly alighted on the bread and fed ravenously on it. A small amount of water was given them, and they were thus left for three days.

At the end of that time they were found to be alive and as active as ever. They were taken out and killed, and their intestinal contents squeezed out on to a clean cover-glass, care being taken not to let their feet come in contact with the cover-glass. Some of the expressed material from the intestine of each one was transferred to sterilized beef-tea, and placed in an incubator. Smear preparations were also made of the expressed intestinal contents, stained, and examined. In one slide were found a number of fine bacilli and spirilla. The spirilla resembled very closely in size and appearance those of cholera; yet one could not be sure until the separation and further testing and growth. At the end of two days the tubes in the incubator were examined and found to be cloudy, and to have a film very similar to the film seen on cholera cultures.

Mounted specimens were made from the film and under liquid, and the field found to be filled with bacilli of varying sizes, micrococci, and spirilla, the latter to all appearances identical with the cholera spirillum. Dilutions were made from the film, and under liquid; and then rolled in tubes. Acid was then added for the cholera red reaction, but with negative results.

At the end of two days the rolled tubes had grown numerous colonies. In two of the rolled tubes the cultures were very much mixed, while in one tube (the one made entirely from the film) the colonies were all uniform in appearance—small, round, grayish white, slightly refracting, liquefying colonies with crenated borders.

Several beef-tea inoculations were made from these latter colonies and placed in the incubator; stab cultures in gelatine were also made. Specimens mounted from these colonies showed long and short spirilla, also the comma shaped bacillus. The spirilla showed a remarkable form in arrangement. The microscopic field appeared to be filled with long, curved, intertwining, and intricately arranged hair like masses, having the appearance of a tuft of curled hair like that used in a mattress. This appearance and arrangement was only found in those specimens mounted from the colonies. It was perhaps the arrangement of spirilla just as they grew. A colony fitted into the wire loop; it was then touched lightly in half a dozen places to a cover-glass, and dried; no other disturbance being made. Invariably this same curled-hair arrangement of these exceedingly long spirilla was found.

At the end of two days the test-tube beef-tea inoculations were found to be cloudy and to have a film.

Examination of the hanging drop showed the field to be filled with comma shaped bacilli and a few spirilla—all in extremely active and lively motion.

The stab cultures in gelatin showed, at the end of two

[1] Read before the Brooklyn Pathological Society, June 14, 1894.

days, growth along the whole line of puncture, with commencing liquefaction at the top Specimens mounted from the beef tea culture showed characteristic comma bacilli and spirilla.

Sulphuric acid added to the beef tea culture gave an intense cholera red reaction.

Bacilli and spirilla of the same shape and size were found in all the beef tea inoculations.

Hydrochloric acid and nitric acid each gave the cholera red reaction; the reaction with hydrochloric acid being the most intense and lasting the longest without fading—at the end of ten days being almost as red as on the day it was made.

The stabs in gelatin continued to grow and liquefy the gelatin in the peculiar glass funnel shaped way at the top of the stab—while the lower part of the stab extended out into the gelatin as a thin, velvety, needle-like growth.

Specimens mounted from the gelatin culture showed the comma bacilli. Thus the recovery of the living spirillum of cholera from flies fed on a culture of cholera proves beyond any doubt how potent and important an agent the common house fly may be in the carrying of this spirillum.

From the fact of the flies not dying within three days, it goes to show that they are able to withstand the toxine of this culture, now two years old, certainly long enough to carry the infecting material great distances, and to deposit it in many places, each of them becoming a focus for infection.

Investigations relating to this subject were conducted by Simmonds, and are recorded in the *Deutsche medizinische Wochenschrift*, 1892, No. 41. Simmonds placed flies in a bottle with cholera fæces for a few minutes, and then allowed the flies to walk over gelatin plates. A series of about nine plates was arranged, and over each the flies were allowed to walk. In nearly all the plates the cholera spirillum was recovered. No attempt was made to isolate the spirillum and grow it in gelatin stab cultures and beef-tea, or to try for the cholera red reaction.

It might be argued that the cholera spirillum, which I recovered from the flies, was conveyed from their feet or their bodies on to the cover glass, the same as Simmonds recovered his spirillum, and thus never entered their intestinal canals. I was very careful that this accident should not occur. Before the flies were inoculated their wings were cut off; and before their intestinal contents were expressed their legs were pulled off and destroyed. The intestinal contents were forced out with sterilized forceps, and only the small drop of liquid at the end of the rectum was used for inoculating the beef tea.

It may be interesting here to note that I was unable to get the cholera red reaction in any of the mixed cultures in beef tea, but never failed to get it in the pure cultures of the spirillum recovered from the flies fed on the cholera.

During my work with this subject I was greatly aided by the many valuable suggestions of Dr. E. H. Wilson, the director of the laboratory, under whose directions all the manipulations were made. I intend to continue my investigations in this line further, and to ascertain whether other bacteria, such as the typhoid, anthrax, diphtheria, and tubercle bacilli, can possibly be carried and deposited in a living state by flies.

Alcohol and Sunstroke.—The late Surgeon Parke, medical officer of the Emin Pasha Relief Expedition, wrote shortly before his death a "Guide to Health in Africa." In speaking of sunstroke he says that he has met with comparatively few cases of it in his African service, and that "he has seen more cases of sunstroke occur during one 'field-day' at Aldershot than during seven years' medical experience in Africa." This immunity from thermal fever he attributes naturally to the use of precautionary measures, the most important of which is abstention from alcohol. "Drink," he says, "is certainly the most powerful predisposing cause of the development of the symptoms of sunstroke."

TWO HERNIOTOMIES IN A CHILD UNDER FIVE YEARS OF AGE—BASSINI'S METHOD.

By SAMUEL E. MILLIKEN, M.D.,

NEW YORK.

THE following case, Stanley H——, who first came to me from Newburgh, N. Y., on May 22, 1890, when a baby of seven months, illustrates some of the difficulties met with in the mechanical treatment of hernia, even at such an early age. Although exceptionally intelligent care was given the case at home, the hernia being retained for some months at a time, and with an otherwise healthy child, the rupture would protrude occasionally almost to its original size.

At the first visit there existed a left oblique congenital inguinal hernia, the size of a small egg, which was easily reducible, but was retained, only after some difficulty, with a "Hank" truss. A celluloid "Hood" truss was applied May 31st, as the worsted truss failed to hold the hernia. The mother was instructed not to remove the truss, even to give the child a bath. Sufficiently frequent visits were made to my office, as would enable me to readjust the truss, and see that the pressure over the inguinal canal and around the pelvis was uniform.

To show the weakened condition of the inguinal regions the child acquired a hernia on the right side, February 29, 1892, when a double truss was applied. This second hernia could not be accounted for by any other reason than the above, as the general health of the child was excellent. The congenital hernia did not improve, and it was decided to perform the radical operation; the right or acquired hernia, however, was easily controlled by a truss.

On June 20, 1893, the reconstruction of the inguinal canal was performed after Bassini's method. The hernia being congenital, the sac was cut off about one inch above the testis, and again flush with the internal ring. The conjoined tendon, and the shelving process of Poupart's ligament, were brought together with interrupted sutures of kangaroo tendon, posterior to the cord structures, while the aponeurosis of the external oblique was closed with a continuous suture of the same material, anterior to the cord structures, thus re-establishing the obliquity of the canal. The skin wound was sutured with interrupted catgut, without drainage. The wound healed under one dressing, without any complications, and the child was sent home on the tenth day after the operation, with instructions to be kept in the recumbent posture for ten days longer, so as to insure firm union of the deeper structures, only a light bandage being worn.

The hernia of the right side, which had been held for so long, was apparently cured, and the truss was therefore left off. However, in a few weeks after the child began to walk, the right hernia reappeared, and a truss was reapplied. With such an unsatisfactory result from conservative measures, I advised a radical operation for the right side, which was not performed until June 21, 1894, one year and one day after that on the left side, which had proven so successful, without any apparatus being worn afterward.

During the administration of the ether for the operation on the right side, the hernia protruded to the middle of the scrotum, and was the size of a large egg. The only difference in technique in this operation, from the one on the left side, was the total extirpation of the sac, as the hernia was acquired and not congenital. The first dressing was changed on the seventh day, when it was found that the catgut sutures in the skin were absorbed and complete union had taken place. The patient was sent home on the ninth day after the operation, with a light bandage, and the parents were instructed to keep the child in the recumbent posture until three weeks had elapsed after the operation.

Conclusions.—1. When any difficulty is met with in the mechanical treatment the radical operation should be performed even in young children.

2. If, after six months or a year, the truss has been steadily worn, and there still exists a flabby condition of the inguinal region, the operation is also indicated.

3. The risk of operating on children, where strict asepsis is observed, is little, if any, more than in adults.

4. The chances for a radical cure in children are greater than in adults, because of the more perfect reparative process at that age.

5. The reconstruction of the canal is, *par excellence*, the operation, and, as shown by Bassini's statistics, has stood the test of time.

6. To obtain the best results a great deal depends upon the surgical technique, and the suture material employed.

7. Drainage should not be employed, if the surgeon is careful to observe the modern rules of cleanliness; for if the wound is infected during the operation it must heal by granulation, and the drainage tube is always an additional source of danger.

8. After primary and complete union of the whole wound no truss is necessary.

36 West Fifty-ninth Street.

IS THERE A NORTHERN REMITTENT (NON-MALARIAL) FEVER?[1]

By NELSON RICHMOND, M.D.,

Fredonia, N. Y.

The importance of the above subject and the interest manifested induce me to write a paper with the same title as that presented to this Society a year ago. In that paper, a year ago, the claim was made that there was a type of fever common to Western New York, and, as I have since learned, more or less common to the entire State, which, in my best judgment, was not typhoid, and to which there was no settled name accredited by all.

It was asserted that some physicians did call this type of fever a mild form of typhoid, others named it gastric, another bilious, another malarial, another remittent, and still another simple continued fever. It was believed that this heterogeneity of names was applied to one and the same fever, and that the lack of text-book information concerning it, coupled with the astigmatism of the observer, made confusion worse confounded. Various authors were quoted to show that either the names had no foundation in fact, or that the symptoms, as portrayed, were not applicable to the fever in question.

This paper will confine itself strictly to the discussion of the identity or non-identity of this type of fever with typhoid.

The burden of proof seems to be that it is not typhoid. But the writer is very anxious to be entirely satisfied in his own mind, either that he is right or that he is wrong. He is the more anxious, after having had nearly fifty such cases, all recurring, and which he never intimated were typhoid, to be clear in his own mind as to the future. These cases carried a period of thirteen years.

The fever in question is usually gradual in its onset, protracted and uneventful in its course, and as gradual in its subsidence. It is confined to neither sex. It has, in my experience, varied in age from five to sixty years. It has a duration from twenty-one to thirty-five days. It seems to run in cycles of seven. The temperature gradually increases in height, day by day, rarely going above 103° F., maintains the highest mark for a few days, and as gradually fades away. The tongue is usually covered with a yellowish-white coating. Sometimes the tongue is clean throughout the entire illness. The countenance is sometimes dull and stupid; again it is little changed. Constipation is usually present, or the bowel may be regular in its evacuations.

The patient is inclined to take things very easy, and not to worry about himself, his convalescence, or things in general.

The skin is usually dull in color or jaundiced in appearance. There is as much emaciation during the progress of the disease as in typhoid.

The pathology of the disease, as far as I am concerned, is a sealed book, for I have never lost a case. There is, moreover, seldom, if ever, any anxiety on the part of the attendant. It is a very comfortable sickness. Errors of diet, during the early stages of convalescence, cause a return of the fever for a few days.

Osler, under the heading "Mild and Abortive Forms of Typhoid Fever," says: "It is very important for the practitioner to recognize the mild type of typhoid fever, often spoken of as gastric fever or even regarded as simple febricula. In this form the symptoms are similar in kind, but altogether less intense than in the grave attacks, although the onset may be sudden and severe. The temperature rarely reaches 103° F., and the fever of onset may not show the gradual ascending evening record. The spleen is enlarged; the rose-spots may be marked; often they are very few in number. The diarrhœa is variable; sometimes it is not present. In such cases the symptoms may persist for from sixteen to twenty days."

I have given this very liberal quotation, not to strengthen my own argument, but to be perfectly fair to those who believe that the fever in question is typhoid. It would be very easy, after reading this description, to argue after this fashion: "What is the use of trying to prove that a disease is less to be feared than it actually is—that it has a much less dreaded name than some contend. Osler is good authority! His description fits nearly enough! Go on and call it typhoid! Your patient will get well and you will get the credit of having excellent success in treating typhoid fever. They will say you never have lost a case, perhaps."

But the above course of reasoning does not satisfy the honest, conscientious practitioner. I will admit, however, that one of the weakest points in the line of argument is the description of the fever. It is so monotonous. Crises and destructive symptoms are conspicuous by their absence.

Let us attempt to portray the symptoms which are absent in this disease, and which are so inseparably connected with the name typhoid.

You will please remark that I said nothing about rose-colored spots in this disease. If they ever have been present they have escaped my observation. There is never any right iliac tenderness. I have seen cases where there was tenderness in the left iliac region. There is seldom any diarrhœa—never any of the pea soup character.

There is never an anxious countenance, rather the reverse, as noted. There is never any sordes on the teeth, never any brown, dry, or cracked tongue—trembling on protrusion. In fact, gentlemen, what is typhoid, and what are typhoid symptoms as generally understood? What does the name convey to your minds but the above line of symptoms—one or all?

We are free to admit, however, that the name typhoid is unfortunate. Should "enteric fever" be generally adopted, and admission made that enteric fever meant an involvement of different portions of the alimentary canal; that Peyer's glands were involved in the serious cases—those accompanied by high temperature, brown, dry tongue, or delirium—then the agitation of this question might be considered unnecessary.

There is no doubt that the South furnishes a habitat for typhoid fever and malarial fever in all its subdivision types of remittent and intermittent varieties. There is no doubt that new sections of the North present the same forms of malarial fever. Malarial fevers were more or less common when this country was new. Cities and certain regions, well defined, present them more or less clearly at present. But the Lake Erie region of Western New York, where this fever has been studied, is a region entirely exempt from malarial influences. The first malarial disease is yet to be treated; the first malarial complication is yet to be observed in years of practice.

[1] Read before the State Medical Society, Albany, N. Y., February 6, 1894.

This, moreover, has been the testimony of physicians who have had a long practice here.

This region may have had malaria fifty or a hundred years ago. It may naturally be inferred that it did. If malaria prevailed and is now absent, may it not have left some disease in its wake? Some disease with its actual malarial germ eliminated? A disease subsequent to the former and depending upon it, but not similar?

If the South is to be credited with these different types of fever; if bilious, gastric, typho malarial, and malarial —without meaning malarial—simply naming it malarial for want of another name—are to be consigned to the Shades, what is the North going to do to offset the malarial types in the South? Is it to be argued that we live in the Garden of Eden? A place where they have only one type of fever and that (under your breath) is typhoid.

It does seem reasonable to me that, as the country is developed and civilization advances; as diseases, under better hygienic conditions and more wisdom in guidance, assume a less serious form, it is a natural inference that instead of losing the type of disease entirely, we should effect a modification of the disease. In this case it would be a change, the true malarial remittent with the germ of Laveran to a remittent of the present time without the presence of the germ. Delay in announcing a positive diagnosis in fevers until the tenth or twelfth day, is always a wise precaution, unless typhoid symptoms proclaim themselves so unmistakably as to admit of no question. A disinfection of the stools of all fever patients is a precaution simple and easy of observance, and restful to the conscience, when a case which admits of doubt develops symptoms unmistakably typhoid.

Desirous of getting many individual opinions upon this question, of being firmly settled in my own mind by a consensus of opinion of the gentlemen present that I am correct; or of being fully convinced, by a full and frank discussion, that the position I have taken is not a tenable one, I stand before you for judgment.

As stated before, I am firmly convinced that terms malarial as loosely applied—typho-malarial, gastric, bilious, and simple febricula—should be blotted from our text-books. The nomenclature should be simplified.

And yet the very fact that these names have crept into our text-books is one of the strongest proofs that there is a fever not typhoid, not malarial.

As suggested a year ago, I believe the name Northern Remittent Fever describes this fever in question, simplifies nomenclature, and is worthy of adoption.

Fredonia, N. Y.

VALUE OF THIRD BLOOD-CORPUSCLE[1] IN TUBERCULOSIS.

By ROBERT L. WATKINS, M.D.,

NEW YORK.

In a paper read before the Pan-American Medical Congress at Washington, in September, 1893, I stated that the third blood-corpuscle is a pathological product. The statement has given rise to criticism, both favorable and adverse. At that time, in my paper, I gave the proofs and reasons for my belief, and will not go over them again here. Arguments and statements deduced from another's experience are never as convincing as one's own, and this is a thing that any physician can test for himself if he has a good microscope.

The granular masses, or third blood-corpuscle, can readily be seen, either alone or in groups. When in groups they are often so pressed together that it may be confusing at first to detect their shape, but a little experience will soon overcome this difficulty, and you will be able to make valuable use of this means of diagnosis.

The third blood-corpuscle is the first indication of tuberculosis, and I assert that *tuberculosis in any form is impossible without its presence in the blood.* It makes its appearance long before the cough, or before any of the formerly recognized signs and symptoms appear. Not only is it found in pulmonary tuberculosis, but in Pott's disease, hip-joint disease, chronic abscesses, and lupus, which diseases are recognized by the best authorities as tubercular. It is also found in some cases of rheumatism and asthma, and often in people who appear perfectly well; but it is always the forerunner of tuberculosis. If it had been present in my own blood I should never have ventured to inoculate myself, as I did some time ago, with tubercle bacilli; and if it had appeared after the inoculation I should have had reason to feel worried. It did not appear, however, and the event has proved that I was justified in my confidence that tuberculosis would not develop.

In an article written recently by Dr. Charles Denison,[1] on "The Diagnosis of Tuberculosis by Tuberculin Injections," he says: "There is an active tubercular state—pre-tubercular state if you wish to call it so—before the tubercle makes its appearance as a factor in the case." (This statement has been made by many others, and, of course, has been known for a long time.) But, still further he says: "Reference is intended to those intricate, slowly acting blood-changes which come under the classification of dyscrasia, which may be, for all I know, the *sine qua non* of the bacillus of tuberculosis."

From my experience I believe the third blood corpuscle to be the *sine qua non* of the tubercle bacillus, and the former to be the means of diagnosticating this dyscrasia which it constitutes; and still further, I believe it to be one of the foods of the tubercle bacillus, and the only *seeable* one in the blood, for I have demonstrated that this germ will live in acute tubercular blood, and have published the same in previous articles. The following cases well illustrate the diagnostic value of this corpuscle.

A few days ago a young lady called upon me to have her lungs examined. She had been staying indoors a few days on account of a cold, but the night before something red came up in her throat like blood. As she had taken some wine that day it was thought it was possibly that, but she was frightened. I examined her chest, and so did another physician. Nothing was found except a little rough breathing. On examination of the blood it was found loaded with these corpuscles, and on that sign I settled my diagnosis of hemorrhage and tuberculosis. Two days after, when going up the Elevated stairs, she had a severe hemorrhage and has had several since. Temperature went up, and now, about two weeks after, she is in bed with high temperature and night sweats. In my experience these cases are not uncommon.

Mrs. H—— came to me with a supposed case of cancer on the forehead. It was a round ulcer about one and a half inch in diameter, one edge looking squamous like, it bleeding very easily, and most painfully sensitive. The neuralgia was quite extensive, radiating from it all over the head. There were also little nodules here and there over the forehead. This had been coming on one year, I believe. A microscopical examination of the blood showed the tubercular third blood-corpuscle present. I then made a diagnosis of tubercular ulcer or lupus, and not cancer. The sore is now healed fairly well, after two months' treatment.

Mr. H——, a single man, came to me only a few days ago, complaining of a cough with expectoration and pains in the chest, most of his family having died of tuberculosis. He only recently buried a sister, to whom he was very much attached, which fact worried him in regard to himself. A physical examination of his chest revealed evidence, in connection with the history, to say that it was the old story of beginning consumption. But on examining the blood no corpuscles were found; and he was put at ease at once, for it could not be tubercular.

Many other cases might be given, but I will only emphasize its value as a means of making a negative diagnosis, *i.e.*, to say that the absence of the third blood-corpuscle from the blood establishes the fact that no tuberculosis is present. The disease with which the patient is affected, therefore, must be of some other nature.

[1] As defined in Landois and Sterling, Physiology.

Clinical Department.

THREE CASES OF NERVOUS DISEASES.

By PHILIP S. ROY, M.D.,
WASHINGTON, D. C.

Case I. *Raynaud's Disease.*—A colored boy, twelve years of age, complained now and then for three months of numbness of the right foot followed by burning pain, particularly marked in the big toe, with occasional attacks of neuralgia in that foot. About two weeks before I saw him he also complained of its feeling very cold—swelling commenced, and he suffered intense pain most of the time. Upon my first examination I found the big toe as black as ink—pressure upon it lessening the discoloration—and voluntary motion seemed lost. On my second visit nutritive alterations had occurred—blood-blisters had formed and several had broken, leaving raw surfaces. The nail was loose and the tissue underneath ulcerated. The asphyxia had continued, and to all appearances gangrene was about to occur.

I had ordered the foot to be elevated and wrapped in cotton-batting, and a soothing ointment applied to the toe. Internally I gave the elix. phosph., iron, quinia, and strychnia, with the twelfth of a grain of morphia to each teaspoonful. I did not see the case again, as the parents could not furnish either the drugs or the proper diet—and I advised that he be sent to the Children's Hospital, or else that one of the physicians to the poor be sent for. He had no fever when I first saw him, but three days afterward, on my second visit, his temperature was 103° F. I never compared the temperature of the two feet.

Case II. *Ménière's Disease.*—A white man, forty years of age, gave me the following history: About a year before I saw him, while at work, he was seized with violent vertigo and fell to the ground. Upon attempting to rise he found it impossible to do so. He was told that his face was very pale and covered with a cold perspiration; was taken home, and for two days, whenever he opened his eyes, all objects seemed to whirl around him. He vomited some the first day.

After two days he could walk about, but found he was very deaf in the right ear, with constant noises in that ear. Since the first attack he has had two others, and in the last of these I saw him; he was then unable to rise, and the slightest movement of his head caused the vertigo to return. His face was pale, with a cold perspiration, and the right ear very deaf. Between the attacks the deafness is much better, though hearing is never entirely restored. I examined the throat and external ear, and could find no disease to account for the vertigo. I therefore conclude that his is a case of true Ménière's disease. He had been told by his former physician that he had bilious attacks.

Case III. *Angio-neurotic Œdema.*—A woman, forty-five years of age, was suddenly attacked with œdematous swelling in one foot, accompanied with gastric pain and nausea. On the following day the other foot became swollen; this lasted three days, when the swelling left the feet and the hands became affected in the same manner. In two days the swelling disappeared from the hands and appeared in the face. At the end of a week all swelling had subsided. The woman looked delicate, but said her health was good. Upon examination I found no disease either of the heart or kidneys. She told me she had had slight attacks of a similar kind. I afterward saw her daughter with a similar attack, except that the swelling was confined to the face and hands and accompanied with nettle-rash, and the gastro-intestinal symptoms were more marked. The daughter's attack lasted ten days—first one part and then another of the face and hands becoming swollen. She had had several attacks in the three years previous. I could find nothing in the diet to account for the nettle-rash, nor did the remedies used for nettle-rash relieve her. In both cases I gave the elix. of iron, quinia, and strychnia, until they were well. I do not know that I have had sufficient opportunity, either from study or observation, to express an opinion upon the subject, but it seems to me that if this disease is sufficiently definite to justify giving it a separate description in medical literature, it is only because in so doing we emphasize the importance of considering the nervous system in sudden attacks of œdema.

The urticaria which sometimes accompanies the disease (as it did in one of my cases) would, as Osler says, make one believe that the patient had simply a case of urticaria—while, as in my other case, purpuric spots would cause one to fear some serious organic disease. These cases of nervous disease, the clinical histories of which differ so widely, are all due, according to our best light at this time, to vaso-motor influences. In the case of Raynaud's disease I exclude all other causes that might produce similar conditions. The more persistently we keep in mind the nervous system in making diagnosis, the oftener are obscure cases made clear to us.

SUMMER COMFORT FOR BABIES: WITH A HINT ON COLDS AND HAY FEVER.

By CHARLES E. PAGE, M.D.,
BOSTON, MASS.

"Man is not by nature a clothed animal," said Carlyle in "Sartor Resartus," and the writer has three little ones, aged respectively nine months, two and a half, and four years, who seem to agree with the Sage of Chelsea; they are never so happy as when they are naked. Four years ago (June 14, 1890) the eldest, a girl, was born, and during all the hot weather we kept her comfortable and happy "in her figure," literally. She was sufficiently blanketed at night and during the cool of the morning and evening, of course; but in spite of Mrs. Grundy she was kept naked much of the time, and with unfettered limbs she was creeping, or, at any rate, hitching, her way across the floor before she was four weeks old. Her unusual strength was due to our practice of non-tending, as well as to the freedom of body and limbs.

The more intelligent of our visitors, to whom she was exhibited, were delighted with the evidence of absolute comfort they beheld, and they straightway manifested a disposition to help their own little relatives as much as they could by stripping off some of the extra folds of flannel under which the little wretches were sweltering and half-smothering. But someone, we never learned who, informed the S. P. C. C. of the outrageous treatment of the little innocent, and looked for our arrest and summary punishment doubtless, and perhaps the adoption of the babe by the State; but it so happened that my little Nursery Guide, "How to Feed the Baby," published in 1882, was dedicated to the Society for the Prevention of Cruelty to Children, and so the President smiled benignly on the good soul who lodged the complaint, and assured her that if Dr. Page's baby died of frost-bite during the summer the case should be carefully investigated!

Something like ten to twelve thousand children have died, under the age of five years, in this city, since the occurrence of the little episode referred to, while our little girl continues to thrive, and to pull off her shoes and stockings the instant she enters the house from her outings, and both she and her little brother have time and again distressed the maid by cutting up that caper and going barefoot on "the Avenue" Numbers two and three have since come to us, and they share their elder sister's dislike for clothes. All three go barefoot in the house all the year around, and much of the time when out, and wear very slight rig at all times.

Next to a bad inheritance—many children being born too tough to kill, while some are so frail by nature that no kind of management will enable them to pull through—the principal causes of infant mortality are: (1) Excessive feeding, digestive capacity being lessened by lack of

exercise and overwrapping; (2) constant tending, and constant lack of natural exercise, so essential to vigor of body and digestive power; (3) excessive clothing, so depleting in many ways to the animal organism, the skin, a breathing as well as an excreting organ, being forced to get on with foul air, instead of fresh, while the pressure of clothing, all the worse if a belly-band is used, interferes seriously with the circulation of blood in the skin, etc.; (4) lack of fresh air in the home, very few homes being sufficiently ventilated.

"Why don't they catch their death o' cold?" Perhaps one reason is that, if the truth were known, none of us catches the disease in that way; it is rather a disease of accumulation of foul matters from the causes already named, and when the system becomes surcharged with filth and certain symptoms appear, we say—those of us who know no better—"He has caught cold!" The fact of the matter is that it is rather a lack of cold, and hence the prediction of Dr. Felix Oswald, that the time will come when every sanitarium will be supplied with an immense refrigerator for the treatment of "colds" (I can never bring myself to repeat the name except with quotation marks). The adult victims of flannels and a diet unsuited to the season, hundreds of whom (physicians as well as laymen, it must be confessed) flock to the White Mountains every summer to avoid "hay fever," might take a hint here and live in comfort in any part of the country. They might go to the mountains for fun, but not as a lot of sneezing, overgrown infants, to babble about the hoped-for specific. How often I have observed a babe who could not suck and breathe at the same time for "snuffles," completely relieved within a half-minute by removing a large share of its clothing, and having a cold, damp towel pressed over the forehead, temples, and top of the head, sending a cool wave in to relieve the congested parts. It should be a cool, damp towel, by the way, not ice-cold for an infant; but the grown snuffling may employ more vigorous measures.

867 Boylston Street.

NOTES ON BRAIN SURGERY.

By W. E. PUTNAM, M.D.,

WHITING, IND.

Case I. *Depressed Fracture of Skull—Amputation at Shoulder joint—Recovery.*—Andy P——, a Pole, aged nineteen, tried to board a freight train and was thrown under the cars. I saw him two hours after the accident, no effort had been made to check the hemorrhage. The left arm was fractured in three places between the wrist and shoulder, and the skin and subcutaneous tissue were destroyed well forward on to the chest. The patient did not complain of pain, and I took it for granted that the railroad shock was to blame for this. After carrying him two miles to my office I amputated the shoulder-joint by a mixed method, using a peculiar-shaped posterior flap and sliding some skin over the pectoral muscles. Amputation completed, my patient continued to sleep on and on, and I began to look for "new worlds to conquer," when I found a three-inch half circular depressed fracture in the left parietal bone. No ether was needed, as the compression had caused what I supposed to be railroad shock. I used a carpenter's chisel (for trephine) and a monkey-wrench (for a mallet). After chiselling away enough of the bone, I used the same chisel to raise the depressed bone. By keeping a continuous stream of water playing on the seat of operation one can see perfectly just how to hold his chisel, there being then little or no danger of injuring the dura mater. The bone was raised, and a strip of iodoform gauze was used as drainage. One hour after the operation the patient sat up and drank a cup of coffee, after which he slid off the operating-table and walked half a dozen steps unaided. In three weeks he was out again looking for work.

Case II. *Compound Fracture of Skull, Opening into the Superior Longitudinal Sinus, with Loss of Two Ounces of Brain Matter—Recovery.*—Swede, aged twenty-three. Two laborers were wrestling for an iron hook, and the hook came down on top of the patient's head, the sharp point entering the superior longitudinal sinus. The patient was comatose when brought to my office. There was a swelling the size of a goose egg on top of the head. A free incision released the pressure on brain, and the patient's heart and respiration improved immediately. When he coughed he literally spat blood from the top of his head, throwing blood fully four feet against the wall of my office. He lost at least two ounces of brain matter. I had not seen very many cases of brain surgery out here in the country, so I packed the wound loosely with iodoform gauze and took my patient twenty miles to the Rush Medical College, in Chicago. Dr. N. Senn put a snap forceps on each of the divided ends of the superior longitudinal sinus, and held them in place with a plaster-of-Paris dressing enveloping the whole head. In four days the snap forceps were removed. In twelve weeks the patient left the hospital, partially paralyzed on one side, but able to walk by the aid of a cane. I wish to record these two simple cases for the benefit of young surgeons who, like myself, are located in country towns, where we are compelled to use our little knowledge and all our courage to save a human life.

AN EASY METHOD OF BATHING IN TYPHOID FEVER.

By WILLIAM B. NOYES, M.D.,

NEW YORK.

Every new medical text-book and periodical accumulates statistics testifying to the brilliant results following the use of cold baths in typhoid fever. The hospitals in which this method is chiefly carried on are almost, without exception, showing a higher percentage of recoveries than ever before under any other plan of treatment.

Why is it, then, that this method is not universally adopted and carried out in private practice? The answer is simple. Easy as it is in a hospital with an abundance of skilled assistance, there is no method of treatment in use so difficult to carry out properly as tubbing in typhoid fever in private families.

As the family bath-room is generally out of the question on account of its inconvenient location, and use by others of the household, it becomes necessary to buy a large portable bath-tub.

Even in cases where there are two trained nurses it is necessary to call in the clumsy assistance of some members of the family to help in the lifting of the patient to and from the tub, and this is a strain on them, and not unattended with risk to the one who is sick.

There is undoubtedly still a widespread opposition among the laity, both educated and uneducated, to the use of "cold baths" in fever. A young physician must have a very strong hold on the family, and enjoy their most complete confidence, to take the risk of the responsibility, if the disease takes a bad turn later from any accidental complications, and even older men will sometimes hesitate.

A physician of high standing and extensive practice in the city recently said to me, "I do not find that tubbing is practicable in private families, much as I would like to make use of it. I have to content myself with sponging and packs, and have had some success with constant use of an ice-coil over the abdomen as a substitute. If the ice-coil acts so well in lesions of the peritoneal coat of the intestines, why should it not have a similar result in lesions of the mucous coat?"

But all these three methods, sponging, wet pack, or ice coil, while they add to the comfort of the patient, do not cause very decided or long continued lowering of the temperature.

Again, one who has had bad results from necessary changing of the position of a patient in an advanced stage of typhoid to examine the back of the chest, or something equally simple, causing disagreeable heart symptoms, will rather dread the process of lifting a pa-

tient out of his bed for any reason whatever, especially if the patient is large and the bed a double one.

The following method, which I once saw used in a hospital in Buffalo, commends itself as a simple solution of the whole problem. I have never seen it published in any medical journal or work, and am sure that it has not often been tried.

It is a very easy thing to slip a rubber blanket under the patient, and raise the two sides and the ends at the foot and head of the bed, nine or ten inches, by a row of pillows, bolsters, sand-bags, or simple boards.

The rubber blanket ought to be of double thickness, as large as can be purchased, and special care must be given to the arranging of the corners. When this is done you have the patient at the bottom of an impromptu bath-tub, into which you can pour water at any desired temperature, and in sufficient quantity to partially or entirely cover his body.

Only two inches of water would be enough to give a cool sponge-bath ten times as efficacious as the gingerly sponging possible under ordinary circumstances, and if the sides and corners are firmly fixed you can easily make this tub hold all the water you desire. The water may be run from the nearest faucet by a rubber tube. I have found it a simpler and equally successful method to carry it in pails and pour it over the patient, starting with tepid and gradually cooling it down to the desired temperature.

The neatest method I have found by experiment is to use a large "watering-pot" with a sprinkler, such as is used for watering plants. This is a method which will not commend itself to those who dislike humble and commonplace methods to accomplish something that more complicated and more impressive methods might do.

I believe this kind of a bath will always be grateful to the patient, and if it is found necessary to use water at a decidedly low temperature, would give rise to less shock than a sudden plunge into a tub filled with very cold water. The effect on the temperature is the same as it would be under the other method with a stationary tub.

The water can be removed, without spilling a drop on the bed, by siphoning with a rubber tube, or dipping with a small pitcher or cup, or sponging. Then the blanket can be dried and left in place, covered by a clean sheet, or better yet, removed and dried in the sun.

All this needs a little care, for it would be a very serious and troublesome accident to soak the patient's bed-clothing and mattress, but the difficulty and risk to the patient cannot be compared with that attending the use of the ordinary tub. And best of all, in those cases where the family or friends must do the work, and the employment of trained nurses is impossible on account of expense, this method can always be successfully used when tubbing would be out of the question.

I have not found one single objection to the employment of the method in private cases, and cannot see why it could not be used in hospitals.

164 West Seventy-third Street.

HISTORY AND TREATMENT OF A CASE OF TRAUMATIC TETANUS AND SEQUELÆ.

By CHARLES J. MONTGOMERY, M.D.,

AUGUSTA, GA.

N——, colored, male, aged thirty-two; occupation, hostler and yard boy. Previous history: No sickness for nineteen years, with exception of one or two attacks of grippe (keeping at work, however, in spite of it), and generally in winter has more or less of bronchitis. History and treatment of case: With a razor he cut a corn with a certain amount of healthy tissue from fifth toe of left foot, causing some bleeding. Kept at work for several days, becoming by degrees very lame. By January 24, 1894, a few days after the injury, lameness and pain in the foot were so great that discontinuance of work was necessary and he went to bed. I was called to see him January 26th. At my direction, before I reached his house, a flax-seed poultice was applied to the foot and fifteen grains of quinine were given. On reaching the bedside I found him suffering considerable pain in the foot, which was somewhat swollen. Fever was present. A simple febrifuge mixture was prescribed containing a small amount of acetate of morphine, and directions were given for him to be sponged with cool water and his bowels moved with a blue pill followed by castor-oil.

January 27th.—He was found to have passed a restless night, and suffered pain not only in the foot, but at the base of the spine and in the left hip. Some pain about the jaws. In addition to the febrifuge mixture he was ordered to take chloral, ten grains, that night, and the same amount the next morning.

January 28th.—Morning of January 28th the jaws were set, but not too close to take liquid food and medicine. Physostigmine salicylate, gr. $\frac{1}{32}$, was given internally, repeated once an hour and again in three and four hours (this being the only preparation of calabar bean obtainable), and a hypodermic of morphine sulphate, gr. $\frac{1}{4}$, was given. Chloral was given again that night, and another hypodermic of morphine. Temperature at this time was $102\frac{3}{5}$° F.

On the morning of the 29th the patient seemed to feel slightly easier, with temperature 101° F. Fever mixture was ordered stopped, but physostigmine continued. Later in the morning he had a violent convulsion, and, having been sent for, I reached the bedside during a second convulsion. Having brought with me a mixture containing chloral, gr. 15; bromide of potassium, gr. 30, in each tablespoonful, I forced his teeth slightly apart with a spoon and gave him a dose of this medicine. I ordered that it be repeated every four hours, and that immediately after each dose he should take morphine, gr. $\frac{1}{4}$, internally. Physostigmine was discontinued. He began to improve immediately after the first dose of the above mixture, and never had another convulsion during the whole progress of the disease. That night he felt comparatively easy and his temperature was 102° F.

On the morning of the 30th the temperature was $101\frac{3}{5}$° F., the man having passed a comfortable night. That evening the temperature was $102\frac{3}{5}$° F., pulse about 110 and weak, and on the morning of the 31st, though a comfortable night had been passed, the temperature was found to be 103° F. I now began to administer infusion of digitalis, in teaspoonful doses, fifteen minutes after each dose of the chloral mixture. The temperature had fallen on the evening of the 31st to $101\frac{3}{5}$° F., and never again rose above that point, which I attribute largely to the continued use of infusion of digitalis. By February 2d the temperature had fallen to $99\frac{3}{5}$° F. in the morning, to rise only to $99\frac{4}{5}$° F. in the evening, with pulse 100. At this time the patient was free from pain and could open his jaws about one inch.

The treatment, in addition to that mentioned, consisted in local hot applications, both wet and dry, to the neck and spine, dressings containing laudanum to the foot, and later in the course of the disease, massage, with hot cocoa-butter, and to move the bowels a rectal injection was given every three days.

Diet consisted of a glass of milk every hour, with whiskey, and when he became able to chew, semi-solid and then solid food was taken.

On February 3d the dose of the chloral mixture was reduced, a dessert-spoonful (or gr. 7½ of chloral, 15 gr. of bromide) being taken at each dose instead of a tablespoonful, except the last dose at night, which was a tablespoonful. Soon the daily amount was still more diminished, though not entirely discontinued, till the end of the third week. About the end of the second week the patient was in a low state of delirium continually, and seemed to be growing weaker, and question of amputation was presented. I decided not to amputate, but dissected away a portion of the scar tissue at the site of the original wound, which had never been an open wound since I had been attending the case. The wound which I thus made, as well as a large portion of the foot, which was

still swollen, was dressed with iodoform gauze saturated with laudanum, and this dressing was continued about a week.

About the fourth week the patient showed evident signs of improvement, which, though slow, were continuous, till the 11th of March, when he complained of passing blood at the end of urination, which was accomplished with a great deal of tenesmus. This condition was followed by pain over the pubes. Suppositories of opium and belladonna afforded great relief, poultices but little; ergotole and fluid extract of cannabis indica were given by the stomach, flax-seed tea prescribed, and the diet reduced again to milk. Examination of the urine, which was very turbid, showed it to contain a large amount of albumin.

Pain in the back and over the kidneys developed later. Œdema of the feet and ankles with great tenderness was present. Dry cups were applied to the loins, and later hot-water cloths, and digitalis and acetate of potassium administered internally; also a few doses of pilocarpine. The temperature during these complications ranged between 99° and 101° F.

The temperature on March 19th had fallen to normal, with pulse at 82, fairly strong, and the urine, though cloudy and containing an abundant sediment, was found to be free from albumin. Improvement from this time has been practically continuous, and the patient now (April 7th), is able to walk about the house and a little out of doors every day, and is steadily gaining strength.

AN UNUSUAL CASE OF TOXIC AMBLYOPIA.

By F. E. D'ŒNCH, M.D.,

NEW YORK.

M. G——, aged forty, came to my office on account of the sudden failure of his sight, which had taken place eleven days previously. The evening before he had been reading fine type without difficulty, whereas the following morning he could not even see the large capitals in the name of his newspaper. As his sight had grown rather worse than better, he sought medical advice.

I found that, even with the aid of his glasses, he could not count fingers at a greater distance than four feet. Distinct sector-shaped atrophy of the temporal side of the optic nerve. Pupils somewhat contracted, but respond promptly to light. Visual field good. There is a marked central color-scotoma, especially for green and red.

The patient has smoked cigarettes since he was eleven years of age, generally about ten or twelve a day, and has also used alcoholic stimulants, though he has not indulged in them to excess. The diagnosis was therefore easy, and the treatment generally adopted in such cases begun. Tobacco and alcohol were entirely withdrawn, and strychnine in increasing doses was injected, at first every day, afterward every other day. Improvement in sight began almost immediately. In a week it was $\frac{8}{200}$, in two weeks $\frac{137}{200}$, in three weeks $\frac{156}{200}$, and so on, until after two months it was $\frac{18}{20}+$, which, in view of the fact that there is a myopia of $\frac{1}{4}$, with an additional astigmatism of $\frac{1}{20}$, may be regarded as normal sight. Faces seem slightly dark still, but he has no difficulty in reading even small print. There has been no change since that time.

Cases of toxic amblyopia are not uncommon, and if sight has not fallen to too low a level, the prognosis is usually favorable. Loss of vision is gradual, and the patient will therefore generally consult a physician before it is too late. The peculiar feature of this case lies in the rapidity with which vision failed, dropping within twelve hours from normal acuteness to counting fingers at a distance of a few feet. Such a rapid loss is seen in acute glaucoma and a few other diseases, but not in amblyopia due to tobacco and alcohol, and so this case seemed to me to be worthy of being put on record.

NOTES ON PELVIC AND GENERAL MASSAGE.

By SARAH E. POST, M.D.,

NEW YORK.

Pelvic Massage.—I have recently attempted this treatment in three cases, in all with a satisfactory result. I have found it possible to propel the contents of the tubes down through the uterus and to secure its discharge without the usual recurring cramps. By cramps, I mean tubal colic. In one case this returned every second or third day; in another it was constant. The pain is in the inguinal region and down the front of the thigh. It seems to be due to traction upon the peritoneal attachments in the inguinal region. It is, I think, not located in the tube itself, for this may be found upon a higher level. The pulling is, of course, to be referred to the contractions and movements of the tube. To secure discharge without contraction and to thus relieve pain became after this discovery the main object of the treatment. In a case of simple catarrh of one side the tube was about the size of the ureter. In another case both tubes were easily found. After treatment they were softer and might escape the touch. This last case had in addition numerous nodules the size of a bean or pea, extending from the side of the uterus, as I recall the case, into the iliac fossa. These nodules also disappeared in the course of six weeks' massage.

In working upon the tubes I move the index-finger of the right hand back and forth transversely across their lumen, beginning at the distal end, carrying the skin, possibly, the whole of the abominal wall, with the finger in this motion, gently persisting over each accumulation where convolution of the tube has occurred. The tips of the two first fingers were used upon the uterus, the kneading being generally restricted to the horns themselves. At the same time the index- and middle-finger of the left hand straightened the uterus and held it upright where there was displacement of the body or neck. In this manœuvre the index-finger was passed in front of the uterus and the middle-finger behind it. In a case without serious displacement no vaginal manipulation was required.

The cases treated had the tubes in place at the sides of the uterus. I would not expect to benefit prolapsed tubes, especially if adherent in Douglas's space.

Incidentally I was made to recognize an unexpected position of the organs. The body of the uterus was entirely above the symphysis, and the distal extremity of the tube pointed toward the anterior iliac spine. This position is, I think, to be traced to our present modes of dress. Many young women have discarded the corset, and all probably hang the skirt from a skeleton waist, giving freedom to the diaphragm, and, as a consequence, elevation of all the abdominal and pelvic organs. In my experience, however, this alteration is recent. Six years ago I found this high position and regarded it as a deformity.

General Massage—Effleurage.—Another matter noted since the publication of my book seems to me of considerable importance. In the course of a bath it has occurred to me to be given the usual long rub, the hands being carried from the distal end of the extremity upward, and from thence downward by a return stroke, equally firm pressure being used. When applied to the arms, I found the heart affected as follows: With the up-stroke came two slow, full beats; with the down-stroke, two feebler beats or two rapid beats followed by an intermission. I am not giving positive details, not at the time having access to a graphic apparatus. The sensation was, however, unpleasant, and, upon my request for up-rubbing only, I secured the results of increased heart pressure—a slowed, strengthened, comfortable pulse. The work upon the lower extremities did not so much affect the heart. Still the influence of the down-stroke was perceptible, and I had it omitted throughout. An element so influential ought, however, to have some useful application. Possibly this may be found in cases of cyanosis, pulsating jugulars, and an overloaded heart.

Progress of Medical Science.

Ovaritis.—Wintcenilz's treatment is the following: Rest in bed; vaginal injections of hot salt-water; scarification of the os uteri twice daily; rubbing of the abdomen with an ointment composed of ichthyol and lanoline in equal parts; and a teaspoonful at bedtime of this mixture for constipation:

℞. Sulphate of soda	ʒ iv.
Sulphur	ʒ j.
Sugar	ʒ v.
Ess. of peppermint	q. s.

In principle this is exactly Goodell's teaching of years ago. In his "Lessons in Gynæcology," p. 386, he says of Weir Mitchell's rest-cure for ovaritis: "I have seen wonderful cures from this treatment, and can recommend it with the utmost confidence. Bedridden patients have been restored to health, and chronic invalids returned to society." Med. Record

Gout of the Intestine.—Many cases of colic, enteralgia, enteritis, and typhlitis, are really gouty manifestations located in the intestine, according to Haig, who uses salicylate of soda with great success for such cases, in doses of about fifteen grains every three or four hours. Drugs like lead, mercury, zinc, and even cocaine, when given to gouty patients, form insoluble urates, and an intestinal crisis may be produced. Buckworth observes that persons do not die of gouty intestinal troubles, and therefore direct ocular pathological proof is wanting. At the same time he emphasizes the fact of their existence. From Haig and Buckworth's observations it may be inferred that in women who have gout or rheumatic gout the so-called recurrent peritonitis, occurring most frequently just after menstruation, is in reality gout of the intestine. There is slight fever or a subnormal temperature, intense pain that gradually diminishes, marked tenderness on pressure, great anxiety and fear of moving or being touched, complete loss of appetite, general prostration and mental depression following, the cycle completing itself in about two or four weeks. Remedies directed to the underlying constitutional state are the only ones that permanently relieve and cure. Med. Record

Tissue Metabolism in Chlorosis.—There is a translation in the *International Medical Magazine* for April, 1894, of a lecture delivered to a private class by Carl von Noorden on "Tissue Metabolism in Chlorosis." The cause of poverty of hæmoglobin in the blood must be due to increased destruction or diminished new formation of the coloring matter of the blood, or to a combination of the two processes. Not one positive sign is known which proves that in chlorosis more hæmoglobin is destroyed than in health. Some distinct points lead to the belief that the normal quantity, and probably much less, is all that is destroyed. The defect is due to some error in new blood-formation. Some restricted exceptions exist in anæmia caused by profuse acute hemorrhage and by acute nephritis. Here there is an œdema of the blood. The plasma is so diluted that the blood-corpuscles swell up and appear relatively poorer in hæmoglobin. In all processes which induce much destruction of this constituent of the blood, as infectious diseases and numerous intoxications, there is principally a destruction of cells (erythrolysis). For a time iron as a remedy fell into disrepute, in consequence of experiments on animals, and a few observations on man. These doubts were more often expressed by physiologists and pharmacologists than by practising physicians. As there was no increase of iron in the urine after the administration of various iron preparations, it was argued that no iron was absorbed. The weak point of this reasoning is of interest. The intestinal mucous membrane is the place of excretion for the iron and not the urine, which is capable of removing only a few milligrammes. Iron which gets into the blood-current accumulates in the liver and spleen, these organs, magnet-like, attracting it. They are the warehouse of the body for superabundant iron, which is given off very gradually by these organs, and is removed by the intestinal juice from the body. How do the iron salts which are absorbed act as remedies? Is the chlorotic organism wanting in atoms of iron around which the hæmoglobin molecule can be built up? Every girl developing chlorosis takes up in daily food more iron than the most extravagant estimate demands. But this iron is exclusively contained in nucleo-albumins. There is no doubt that the healthy organism takes up iron from nucleo albumins and employs it for the manufacture of hæmoglobin. Why does not the chlorotic patient do the same? Is absorption at fault? On the contrary, absorption is excellent. Iron is absorbed, but is not used. There is diminution of the energy of growth in the hæmatopoietic organs (bone marrow), resulting in the non utilization of the ferruginous nucleo-albumins which are brought by the blood. So far everything is proved. Now for the region of hypothesis. Let us suppose that the iron salts circulating in the blood effect a stimulation of the hæmopoietic cells of the medulla of bones, and that the result of this stimulus is an amelioration of the constitution of the blood. On the other hand, the nucleo-albumins containing iron which are circulating in the blood exert but a weak stimulus on bone marrow. Experience proves that in the treatment of chlorosis any iron salt is more efficacious than the ferruginous nucleo-albumins, like hæmoglobin, hæmotogin, hæmogallol, etc., which pure theorists have tried to foist on the profession. Arsenic gives good results. Yet success is much greater when combining arsenic and iron. Practical experience proves this is the best plan. At health-resorts where there are carbonated ferruginous springs, resident physicians do not recommend these waters to chlorotic subjects, but advise the mineral waters of Levico or Roncegno, which contain arsenic and iron. These substances are closely allied chemically, and exert on the cells an effect that is only quantitatively different. Med Record

Idiopathic Hypertrophy of the Heart and Degeneration of Heart-muscle.—An address upon the foregoing subject, given in abstract form in the *British Medical Journal*, April 7, 1894, was delivered at the International Medical Congress, in Rome, by Dr. S. Laache, of Norway. Idiopathic hypertrophy is defined as enlargement of the heart without obvious anatomical, or rather, mechanical obstacles to the circulation. The valves are either intact or affected only by lesions in nowise proportionate to the clinical symptoms. The etiology presents some points of hygienic or social interest. The chief predisposing causes are heredity, and those conditions which betray their influence by defective nutrition. Among determining causes the most important are alcoholism and excessive muscular exertion. Beer-drinking is the chief cause of pure idiopathic hypertrophy. Athletics has been considered the origin of much cardiac hypertrophy. It is now conceded that if the athlete is of proper age, properly trained, and abstains from alcohol, trouble with the heart does not necessarily follow a reasonable amount of indulgence in sport. Physical overstrain weakens the heart, and so does intellectual overpressure. Modern life in cities is not conducive to that mental repose which is necessary to secure normal circulation. The hygiene of the heart is sadly neglected. Sudden death from cardiac trouble seems to be increasing in frequency. Yet often the diseased heart possesses a power of resistance that is almost incredible, and which led Haller in his day to apply to it the epithet *ultimum moriens*. In Pepper's "System of Medicine" Osler states that symptoms are not necessarily present in simple cardiac hypertrophy, since this is a conservative process and almost always an unmixed good. The pulse of hypertrophy not dependent on valvular lesion is usually firm, full, and strong, of high tension, and regular. It may be increased in frequency, but often is normal. A frequent symptom is an unpleas-

ant feeling about the heart, a sense of fulness and discomfort. Flushings of the face, noises in the ears, flashes of light, and headache are not uncommon. The course of an ordinary hypertrophy divides itself into three stages: the period of development, which varies with the nature of the original factor in development; the period of full compensation, the latent stage, during which the heart's vigor meets all the requirements of the circulation, and this second stage may last indefinitely; and the third period is what is called the breaking of a compensating hypertrophy. It may come suddenly during extra exertion, and death follow from acute dilatation; or more commonly it takes place slowly, and results from degeneration and weakening of the heart-muscle, with consequent dilatation and all its evils. The treatment of hypertrophy consists largely of measures directed toward its maintenance in a degree proportionate to the extra work which the heart has to do. The utmost moderation in food, drink, and exercise must be enjoined. Quiet and regular habits are imperative. Excesses of all kinds quickly lead to impairment of the heart's action. In the hypertrophy associated with arterial and renal disease a special danger exists in the tendency to rupture of vessels. Vigorous heart-beat with very high tension in the peripheral arteries indicates mischief which may be met by prompt measures to reduce the high pressure. A brisk cathartic may avert apoplexy, and the old-fashioned method of bleeding is often justifiable.

The Treatment of Pruritus.—Leloir recommends electricity in pruritus of all types—anal, vaginal, and general—and uses the electric breeze of the statlc machine with the happiest results. Mercurial ointments give immense relief for the time being. Crocker speaks in praise of ammoniated mercury, gr. xx. to ʒ j. of benzoated lard; also the yellow oxide of the same strength, and calomel, gr. x. to ʒ ss. to ʒ j. External treatment is of great service in alleviating the itching, even if it does not cure the disease. Jackson advises general baths with soda (℥ viij. to x. to 30 gallons), or nitric or hydrochloric acid (℥ j. to 30 gallons). After the bath the body is to be dried by wrapping it in a warm sheet and patting it dry; then the skin should be smeared with vaseline and powdered with corn-starch from a dredger. Bulkley first suggested cannabis Indica, ten minims three times a day, in water after meals, gradually increasing the dose to twenty or thirty minims. For children Ellis recommends the daily use of tepid alkaline baths; quinine and cod-liver oil for the strumous; nitro muriatic acid in sarsaparilla, taraxacum, and Fowler's solution. Bronson finds a solution of hydrogen peroxide of great value in general pruritus; also an aqueous solution of ozone, used as a toilet wash, and known commercially by the name of "aquozone." Faradism is often successful in senile pruritus, applied only to the spine by means of a brush electrode. The cold douche is another remedy in the same line that is sometimes of benefit, and is best used in the morning. In local and general pruritus the following formula for external application has given excellent results:

℞. Acid. carbolic ..... ʒ j.—ij.
Liq. potass. ..... ʒ j.
Ol. lini ..... ℥ j.
M. Sig.: Shake before using.

Dust Diseases and their Prevention.—The relation of dust to pulmonary affections is a subject the investigation of which has already led to many valuable practical results, and which is still far from being exhausted. Dust of a non irritating nature is necessarily inhaled into the lungs of town-dwellers, where it causes the dark and mottled aspect so familiar on the post-mortem table. The irritating dust, on the other hand, which is encountered in many occupations, leads to more or less serious pathological conditions of the pulmonary organs. Thus it may cause bronchitis, acute and chronic, emphysema, asthma, bronchiectasis, fibroid conditions, hypertrophy of bronchial glands, and phthisis, with a whole chain of attendant vascular disturbances. These dust diseases, or pneumokonioses, are met with, as every one knows, among millers, masons, miners, grinders, and others who follow occupations which habitually expose them to a dusty atmosphere. This injury is, in the first place, mainly mechanical, and usually has a direct relation to the texture of the material which furnishes the dust. In this way steel particles are more deadly than stone, and the latter than flour. In other cases the injury to workmen is partly mechanical and partly chemical, as in the lead enamel grinding trade. So much for the evil, which is obvious enough, and needs little more than the above passing reference. A great deal more discussion is wanted, however, when we inquire as to what has been done in the way of prevention. The two great preventive measures are undoubtedly free ventilation and the introduction of wet processes. It is a well-known fact that the substitution of wet for dry grinding in Sheffield was followed by a great fall in the number of deaths from phthisis. A similar principle might be applied with advantage in other trades. For instance, the dust raised in grinding lead enamel is of a peculiarly deadly nature, since it acts both as a mechanical and a poisonous irritant. Lead enamel is practically insoluble, and there is no doubt that many of the steps in its manufacture could be carried out equally well by elutriation and other wet methods. Ventilation, again, is often defective in the enamel factories. The beneficial action of a free circulation of air is probably due to the dilution and the removal of noxious particles. Nowhere has the improvement of ventilation been followed by better results than among our mining population. To take a single instance: it has lately been officially reported that in the mining division of Cornwall the proportion of deaths from phthisis or "miner's disease" has of late years decreased. This satisfactory result appears to be due chiefly to the better underground ventilation, consequent on the introduction of boring machinery and of other improved conditions. Some years ago the whole question of miners' phthisis was closely investigated by the Royal Cornwall Polytechnic Society, who offered prizes for sound information, and obtained a quantity of valuable matter, which is to be found in their annual reports of that time. This public-spirited action affords an excellent illustration of the good that can be effected by local bodies, if they will only be content to confine their scientific ardor to subjects at their feet, so to speak, and within the grasp of an average comprehension. Conducted on such lines the work of provincial associations is likely to afford substantial help in arriving at precise facts and figures with regard to dangerous employments. They will be also in a position to acquire exact information as to methods, and to suggest improvements in trade processes. Their data would then be simply invaluable to the scientific man, in whose hands the application of preventive measures must ultimately be placed. When thoroughly sound conclusions have been arrived at it is the duty of legislators to frame laws in accordance with the facts submitted to them. It is a well marked tendency of modern legislation to make compulsory all measures that have been shown to be clearly preventive. Bearing this in mind, one may safely assert that the compulsory legislation of the future will find a large and useful field, so far as the happiness of many members of the community is concerned, in the control of dust-producing occupations. Whatever may be done, it is unlikely that the whole of the mischief could be abolished in each particular trade. The risk, however, could and should be reduced to its minimum. The steady aim of the sanitarian in dealing with dust diseases will be levelled at the preventable margin, and he will not fail to make due allowance for the unavoidable residuum.—*Medical Press.*

Dr. Baillon, the well-known botanist of Paris, has been elected to foreign fellowship in the Royal Botanical Society of London.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 14, 1894.

THERAPEUTICS AT THE INTERNATIONAL MEDICAL CONGRESS.

IT may happen that the most successful and largest medical congresses are not particularly rich in therapeutic work. Yet, after all, when the heat and smoke of the day are cleared away, one feels that the important query is this: Has anything been said or read which will make the treatment of diseases more sure and effective?

We have been looking over the records of the International Congress at Rome, and have tried to find what practical therapeutical suggestions were made at that time.

The results of our study, which has been facilitated by a critical review in the *Gazette des Hôpitaux*, have not been very fruitful, nor yet altogether barren. For example, Dr. Petresco, of Bucharest, comes forward again with further facts regarding his treatment of pneumonia with large doses of digitalis. He has employed his method now for thirteen years and treated 1,192 cases, and he has reduced the mortality to 1.22 and 2.66 per cent., while under other treatment the mortality ranges from 7.15 to 35.50 per cent.

A year ago we discussed Petresco's method, which consists of giving eight or ten or even twelve grammes of digital leaves in twenty-four hours. According to the author, it invariably jugulates acute lobar pneumonia in a few days.

Dr. Goffredi, of Naples, calls attention to the value of lactose as a diuretic, particularly in heart disease. It is not so effective in nephritis. Diarrhœa is sometimes caused by the lactose.

Dr. Pucci praises very highly the use of phenocoll in malaria. He gives from one-half to one gramme a day.

After having broken up the paroxysms, the drug is continued five or six days in association with quinine or arsenic. It is also very useful in malarial neuralgia.

A curious contribution to therapeutics is that of Dr. Sanchez Herrero, of Madrid, who recommends a solution of bromide of potash, 50; iodide of potash, 5; and water, 500, in the treatment of epilepsy. Dr. Herrero is evidently not familiar with some of the very ancient formulas for epilepsy, including that of Brown Séquard. We should add that the doctor adds to his treatment hypnotic suggestion twice a week, and that he has cured 19 cases out of 30.

Dr. A. Murre, of Bologna, makes a protest against the abuse of cold water in the treatment of chlorosis, but at the same time thinks that cold water properly used is better than drugs in this condition.

Dr. Tison thinks that the nitrate of aconitine is useful in facial erysipelas, shortening the attacks and lessening the pain. He gives gr. $\frac{1}{60}$ ten times a day.

Von Ziemssen, of Munich, would have us return to the use of transfusion of blood, particularly in grave anæmias.

The best method is the arm-to-arm one without defibrinating, but if this is not practicable he recommends subcutaneous injection of non-defibrinated blood. This ought to be given under chloroform and followed by massage, as the process is very painful. It is safe to say that a treatment involving regular anæsthetization of the patient will hardly become popular, and certainly is not safe.

DR. MITCHELL ON INSANE ASYLUM MANAGEMENT.

THE address of Dr. S. Weir Mitchell before the American Medico Psychological Association, at their meeting held in May last, has just been published (*Journal of Nervous and Mental Disease*), and it promises, we believe, to excite wide attention. Dr. Mitchell, with the consent of the Association, took the opportunity to arraign, in the severest manner, the present methods of caring for and treating the insane in America. He undertook the task evidently with reluctance, but with a keen sense of the duty before him and of the opportunity offered by the very generous attitude of the asylum superintendents. The speaker fortified himself well for his work, not only by a personal knowledge, but by letters sent to him from nearly thirty of the leading neurologists and alienists of this country, giving opinions and suggestions regarding the present methods of managing asylums.

It is unnecessary to say that Dr. Mitchell's address is throughout an interesting and scholarly one, full of wit and satire, yet withal not unkindly or in any way unjust or offensive. And, after all, it is the Boards of Managers, the public, and the politicians which receive the severest castigation. We wish we had space to quote the criticism upon managing boards, their make-up and their methods. There are, of course, good as well as bad managers, but it is true that in the majority of cases the modern asylum trustee has not the slightest conception of the higher and truer needs of a hospital for the insane. The prevailing idea is to look after the farm, the kitchen, and laundry, and to get materials for a satisfying annual report with forty per cent. of "cures" and a balance to the credit of the institution.

As for the medical superintendents: their weakness, he says, lies in this, that they work apart from their fellows and are not in touch with the medical profession as a whole; that they aim only to run smoothly a great hotel or boarding-house, knowing little and contributing nothing to psychology or psychiatry, and least of all to therapeutics. Dr. Mitchell's final words furnish us a picture of the ideal hospital for the insane. We read it

with delight at the skill of the writer, as he portrays what to his fancy the present should, and the future may, furnish us. But we feel also a sense of sadness at the difference between the ideal and the real. And we think of our own State Lunacy Commission laboriously aiming to cut down the price of brooms, and utterly forgetful of the higher needs of hospitals for the insane.

We trust that Dr. Mitchell's address will awaken not only the conscience of those now responsible for asylum management, but will stir the public heart until the politics, penuriousness, and incapacity that surround so much of American asylum work are abolished.

THE POWER OF A DIPSOMANIAC.

Peter the Great was an enormous consumer of brandy, and, to drop to modern times, Webster was not strictly temperate, and Lincoln had some very able whiskey-drinking generals; but history furnishes no account of dipsomaniacs who were sound in judgment or great in action. Dipsomania is a morbid condition, characterized by the irresistible obsession and impulse to drink, coming on in attacks during which the patient abandons himself entirely to the craving for liquor. Dipsomaniacs may appear perfectly rational between their seizures, and may transact business with apparent soundness of mind. Nevertheless, they still possess something unbalanced and false in their mental make-up. Dipsomania always occurs in persons who have a psychopathic constitution; they belong to the class called by the French the *degenerate*. Consequently, one will always find in their character some peculiarity which puts them out of the ordinary, and among a class which we cannot entirely trust. Their eccentricities may be harmless, or may be shown in some moral perversion or monomaniacal enthusiasm. A person who has dipsomania is essentially one whose judgment is weak and whose actions may be erratic, perhaps picturesque; or, on the other hand, foolish, cruel, or criminal.

The reports of the present extraordinary riots and disturbances which have paralyzed trade, destroyed property, and terrorized whole communities, is shocking, yet, under the circumstances, not so very surprising. Such men sometimes have a power of eloquence and organization sufficient to accomplish at times a great good, but more often enormous evil. But it shows something vitally defective in the local government of some of our cities and States, when an irresponsible enthusiast can bring about such things as we have witnessed in and about Chicago during the past fortnight.

ANOTHER NEW HOSPITAL.

The Chambers Street Hospital is about to move from its present quarters into a new and larger building at the corner of Hudson and Jay Streets. The present hospital has been occupied since 1875. It was formerly a police-station, and has become quite inadequate for the work demanded. The Chambers Street Hospital has for many years done an immense amount of valuable work, more particularly in surgical and accident cases. The annual number of visits to it is over sixty-five thousand, and three ambulances are kept busy night and day. The new hospital is a large five-story building, fire proof, and equipped with every modern convenience.

Along with the excellent philanthropical results of the Chambers Street institution, there is another which most will consider minor and incidental, viz., it has rendered a down town practice impossible. In other words, accident and emergency cases are all taken promptly to the hospital and never to a private office, however well able to pay the patient may be. Of course, if this is the best thing for the people as a whole, the physician must submit. At any rate, institutional medicine has full swing in the down town district.

News of the Week.

Dr. Solomon Van Etten, one of the oldest and best-known physicians in Orange County, died suddenly at his residence in Port Jervis, July 7th, of apoplexy. He was sixty-five years old. He was a graduate of the Albany Medical College, class of '55. During the civil war he was brigade surgeon in General Terry's division, and retired from the service with the rank of Lieutenant-Colonel. He practised medicine in Port Jervis until his death. He ran twice for Assembly on the Republican ticket, was United States Medical Examiner for the Orange and Sullivan district during the administrations of Grant, Hayes, and Harrison, and two years ago was elected Medical Director of the Grand Army for the department of the State of New York.

Dr. W. R. Adamson, of this city, died on July 6th at his summer residence at Lake George. He was forty-two years of age, and was born in Stockton, England.

Births and Deaths.—*The Southern Medical Review* is a new monthly that comes to us from Houston, Tex. It is edited by Dr. N. J. Phenix, but arises from no ashes. *The Railway Surgeon* is the title of a new monthly. The *National Medical News*, the *Epitome of Medicine*, the *Country Doctor*, the *Weekly Medical Bulletin*, the *American Gynecological Journal*, and the Atlanta *Journal of Surgery, Gynecology, and Obstetrics* have ceased to appear.

The Plague.—The bubonic plague, the terror of Europe even to the close of the seventeenth century, has again made its appearance in China, where it is more or less endemic, as it is in Asia Minor. The *British Medical Journal*, while admitting the vividness of the picture drawn by Defoe, points out that "while there is much exaggeration in his 'Plague of London,' his description of the phenomena of the disease is fairly accurate. The present title is derived from the swelling in the groin. In the earlier plague, a similar swelling in the axilla was a frequent symptom. The disease is a rapid, malignant, contagious fever, accompanied by buboes, carbuncles, and livid spots. At least two thirds of its victims die. Its symptoms are violent headache, accompanied with violent tremors alternating with intense heat. The eyes become red and assume a ferocious aspect, resembling those of victims of hydrophobia. The pain extends from the head to the spine, joints, and limbs. Then follow vertigo and delirium. The tongue is dry and yellowish. Respiration is difficult, nausea occurs, but rarely vomit-

ing. The disease runs its course in from three to seven days. The patient often dies in a few hours. The first known appearance of the plague in Europe occurred 430 B.C., when it depopulated Athens, reaching there from Egypt by way of Libya. It was brought into Europe by the returning crusaders, and has frequently appeared since, always coming from some part of the Turkish dominions. It appears in lower Egypt, Syria, and Turkey about every seven or ten years. It has often made its appearance in London, the most frightful visitation being in A.D. 430, when there were scarcely enough living left to bury the dead in all England. In A.D. 716 Constantinople lost 200,000. In 1348 Germany lost 90,000. It has scourged various parts of Europe from time to time since, carrying off hundreds of thousands at each visitation. In Egypt 800,000 died in 1792. The latest visitation of which we have an account at hand was in 1813, when it was exceedingly fatal in Egypt and in Malta."

American Academy of Medicine—The nineteenth annual meeting of the American Academy of Medicine will be held at the Waumbek, Jefferson, N. H., on Wednesday and Thursday, August 29 and 30, 1894. The greater part of the time is to be devoted to the discussion of certain problems relating to the medico-social relations of the medical profession to the "dependent classes." Arrangements have been made for a special excursion from New York and Boston and return at reduced rates. A choice is offered of an eleven days' excursion, including most of the expenses, or of returning immediately at the close of the meeting, and is open to anyone desirious of attending the meeting, whether member of the Academy or not. Any additional information about the meeting or the excursion may be obtained from Charles McIntire, *Secretary*, Easton, Pa.

American Electro Therapeutic Association. — The fourth annual meeting of the American Electro-Therapeutic Association will be held in New York, September 25th, 26th, and 27th, at the Academy of Medicine.

Salicyd Chloroform is a combination of chloroform with salicyd. It is a crystallized substance, which on warming gives off perfectly pure chloroform. Dr. Hans Schmid has used it in one hundred and sixty-six narcoses, and recommends it as being safer and more pleasant than the ordinary preparations.

The German Commission of Anæsthesia.—At the Twenty-third Congress of the German Surgical Association it was voted to continue the general investigation into the statistics of anæsthetics which the society has been engaged in for the last four years. Reports are desired until March 15, 1895. Consideration of the following points is especially urged: Specification of the time of observation, of the anæsthetic used, and the number of times exhibited; reason for administration; apparatus used; duration of unusually prolonged narcosis; amount of material used; the concomitant use of other drugs, as morphia, and the amount; undesirable phenomena or sequelæ.

The Faculty of Fort Wayne College of Medicine have adopted a three years' graded course, the work done in which is based upon the four years' graded course recommended by the College Association.

A Death from Hydrophobia.—A case of death from hydrophobia has occurred at the Pasteur Institute; but the patient was already in a hopeless condition at the time he was admitted. Mr. Walter E. Orcutt, a hotel keeper of Northampton, Mass., was bitten on the wrist by a pet dog on May 23d, and although the wound was very slight, he took the precaution of having it cauterized. It healed perfectly, and he thought no more about the matter until June 23d, when he was seized with alarming symptoms, and was at once brought to the Pasteur Institute in New York. His friends were assured by the physician in charge, Dr. Labadie (Dr. Gibier's assistant), that no treatment would now be of any avail, and he died on June 26th. In this instance, the more violent manifestations of rabies were in a great measure lacking, but the patient rapidly succumbed to paralysis of the nervous centres.

American Public Health Association.—The Twenty-second annual meeting of the American Public Health Association will be held in Montreal, Canada, on September 25 to 28, 1894, under the presidency of Dr. E. P. Lachapelle, of Montreal.

The Massachusetts State Board of Registration of Physicians and Surgeons.—The governor has made the following appointments for the first Board of Registration under the new Medical Practice Law: E. J. Forster, of Boston, for seven years; W. P. Bowers, of Clinton, for four years; D. B. Whittier, of Fitchburg, for five years; A. C. Walker, of Greenfield, for one year; S. H. Blodgett, of Cambridge, for three years; C. Edwin Miles, of Boston, for two years; A. L. Chase, of Randolph, for six years. Drs. Forster, Bowers, and Walker are members of the Massachusetts Medical Society; Drs. Whittier and Blodgett are members of the Massachusetts Homœopathic Society; and Drs. Miles and Chase, of the Massachusetts Eclectic Society.

Harvard Medical School.—The graduating class of the Harvard Medical School this year contained one hundred and twenty-seven men, and was the largest class ever graduated.

Unsanitary Edgewater.—The Richmond County (N. Y.) Medical Society, in a series of resolutions, declare that small-pox is prevalent there in consequence of the neglect of the health authorities, that the village for the same reason is in an unhealthful and filthy condition, and appoint a committee to co operate with the president of the village, that the necessary reforms may be made.

The Colorado State Medical Society.—At the recent meeting of the Colorado State Medical Society, held in Denver, June 19, 20, 21st, the following officers were elected for the ensuing year: *President*, Dr. Hubert Work, Pueblo, Col.; *First Vice-President*, Dr. J. R. Robinson, Colorado Springs; *Second Vice-President*, Dr. E. Stuver, Rawlins, Wy.; *Third Vice-President*, Dr. Laura Liebhardt, Denver, Col.; *Treasurer*, Dr. W. F. McClelland, Denver, Col.; *Corresponding Secretary*, Dr. C. K. Fleming, Denver, Col.

Strophanthus is a valuable and safe remedy. It is a cardiac tonic, a diuretic, and quickly relieves præcordial pain and dyspnœa. The tincture is the best preparation. It should be given in small (ɱij) doses, gradually increased and combined with stimulants and

anti-spasmodics, such as ammonia and ether. It is a most useful drug in aortic regurgitation, as its power of lengthening diastole is not so great as digitalis, nor has it so marked a cumulative action; and any danger which may lurk in its administration is considerably lessened by its combination with ether.—Dr. Taylor.

New York Polyclinic.—Dr. J. Riddle Goffe has been appointed Professor of Gynecology in the New York Polyclinic.

On Periodical Testing of Eyesight in Schools.—Mr. Priestley Smith read a paper on this subject recently before the Ophthalmological Society of the United Kingdom. Authorities, he said, were agreed that advantage would accrue from an annual testing of the eyesight of school children, and several commissions had spoken to this effect, and formulated definite proposals. Hitherto no considerable advance had been made toward this end, for the proposals usually put forward had been that the refraction of every scholar should be ascertained once a year by the school doctor. It would be a long time before every school had its school doctor and every school doctor was an efficient oculist. The necessities of the case could be met more easily, and would, he hoped, be so met in a large number of schools throughout the country before long. The governors of King Edward VI.'s schools in Birmingham, which comprised about twenty-two hundred boys and girls, aged from eight to nineteen, had established three years ago a periodical physical examination of the scholars in regard to height, weight, chest measurement, eyesight, and hearing. The eyesight test was carried out by certain teachers appointed for the purpose. It made no pretence of being a scientific proceeding; there was no attempt to estimate refraction or diagnose disease. Any such attempt was worse than useless unless the examiner were an ophthalmic expert. In every case in which the vision in either eye was less than six-eighteenths, an intimation of the fact was sent to the parent, and with him rested the responsibility of obtaining the necessary advice and choosing the adviser. The Anthropometric Committee appointed at the last meeting of the British Association for the Advancement of Science, having Professor Cleland and Professor Windle for its Chairman and Secretary, had lately issued an inquiry to a large number of schools as to whether and to what extent periodic physical examination of the scholars was in force. From the replies received it appeared that the eyesight was tested in eight out of four hundred and eighty-three boys' schools in England, Scotland, and Ireland (Whitaker's list); and in six of one hundred and twenty-nine girls' schools in England; while color vision was tested in three only of the whole number. Many of the principals, however, expressed willingness to take up anthropometric work on receiving directions for carrying it out. The speaker laid before the meeting the printed directions which had been drawn up, and which were to be sent, in the first instance, to about two hundred schools. The eyesight test included in this scheme was practically the same as already in operation in the King Edward schools in Birmingham. It involved practically no expense and very little trouble to the school authorities, and it interested at least one teacher in every school in the eyesight of the scholars. In advocating this system, the speaker did not in the least undervalue the importance of a thorough medical examination of schools, and he knew that many schools already had duly appointed medical officers competent to deal with errors of refraction, but these were exceptions. By making this simple eyesight test a part of the anthropometric scheme now being so energetically pushed by the Committee of the British Association they would, he was confident, attain the desired end in a large number of schools where it could hardly be attained in any other way.

Lightning Stroke.—"Ball lightning," the *fulmen globulare* of the older meteorologists, is the most dangerous and destructive of the forms which lightning is known to assume. Fortunately, however, it is the rarest. A narrow escape from death by its stroke occurred lately in the person of a distinguished surgeon of the Belgian school, Dr. L. Dandois, Professor of Surgery in the University of Louvain, who had gone to the neighboring town of Linden to visit a patient, and on his return, having alighted from the train to continue his homeward journey by road, was overtaken by a heavy thunderstorm. The sky became as [illegible] difficult for him to

tions; and therefore that the nucleins from different sources would be very different, *e.g.*, that from yeast different from that from the spleen or the thyroid gland, etc., the number of kinds being limited only by the number of different cells.

It is the chemical basis of the nuclei of the cells, sometimes called by the histologists chromatin, from the ease with which it takes up staining materials. Chemically, the nucleins are proteid bodies containing a large amount of phosphorus, existing in the form of nucleinic acid, this acid being the same in all nucleins; but, combined with different bases gives us the different resulting nucleins. On reduction and recomposition they yield some of the so-called xanthin bodies. In general they are insoluble in dilute acids and soluble in dilute alkaloids, and resist peptic digestion.

Some substances histologically nucleins do not yield any xanthin base, and such are now called para-nucleins, and some of these are the antecedents of the true nucleins.

Some nucleins are combined with albumins forming nucleo albumins. Miescher was the first to study appreciatingly the nucleins, and was the one who named them.

He prepared his specimens for investigations from pus corpuscles, and later from the yolks of eggs.

In 1874 he made his most important contribution to the knowledge of nucleins by working with the spermato- [illegible]

stopped or cured by medicines. 3. [illegible] be done at the outset of an attack is to send the patient to bed, so as to save strength from the beginning. 3. No strong purgative medicines are desirable. 4. As the fever develops and the strength grows less, light food should be given at short intervals—*i.e.*, water, toast water, barley-water, milk and water, light broths (not made too strong or too gelatinous). 5. If there be restlessness or much agitation of the nerves, wine (port, sherry, or claret), or brandy in moderate doses at short intervals. This must be directed medically, but in general it may be said that the amount required is that which induces repose and sleep. 6. The bowels may be left to themselves. If unmoved for twenty-four or thirty-six hours a lavement of warm water may be necessary, but this will be directed medically. 7. The restlessness or wakefulness in fever is best remedied by the careful giving of wine or spirit with the food, or in hot water. Sedatives such as opium are inadmissible—mostly injurious. 8. The bedroom to be kept at a temperature of 62 to 65° F.

9. Great care is necessary to keep the bed clean and sweet. This is most easily done by having a second bed in the room, to which the patient can be removed for two or three hours daily, while the other is thoroughly aired and the linen changed. 10. All fatigue to be sedulously avoided. No visitors admitted, and no other person but a nurse and one attendant to help her. 11. Patient's room never to be left unattended for a moment, as in the delirium of fever patient may jump from bed and injure himself. 12. As to medicines and the treatment of complications, the immediate medical attendant must be responsible. 13. As it is possible that the discharges from the bowels in typhoid fever may be a source of contagion, it is desirable that before being thrown down the closet they should be largely mixed with Condy's fluid or some other disinfectant. On the same principle the strictest cleanliness must be observed in the sick-room. 14. There is no reason to believe that typhoid fever is contagious from person to person, in the ordinary way. The largest experience shows that it does not extend, like an ordinary contagious disease, to nurses or others attending upon patients suffering under the disease.

[illegible] at the Wentworth, Jefferson, N. H., on Wednesday and Thursday, August 29 and 30, 1894. The greater part of the time is to be devoted to the discussion of certain problems relating to the medico-social relations of the medical profession to the "dependent classes." Arrangements have been made for a special excursion from New York and Boston and return at reduced rates. A choice is offered of an eleven days' excursion, including most of the expenses, or of returning immediately at the close of the meeting, and is open to anyone desirous of attending the meeting, whether member of the Academy or not. Any additional information about the meeting or the excursion may be obtained from Charles McIntire, *Secretary*, Easton, Pa.

American Electro Therapeutic Association. — The fourth annual meeting of the American Electro-Therapeutic Association will be held in New York, September 25th, 26th, and 27th, at the Academy of Medicine.

Salicyd Chloroform is a combination of chloroform with salicyd. It is a crystallized substance, which on warming gives off perfectly pure chloroform. Dr. Hans Schmid has used it in one hundred and sixty-six narcoses, and recommends it as being [illegible]

Awards at the International Exposition of Hygiene in Rome.—The German exhibitors figure prominently in the official list of awards made by the jury of the International Exposition of Hygiene held concurrently with the International Medical Congress in Rome. From the report of the Exposition already given in our columns, the reader will be prepared to find that the Imperial German Gesundheitsamt received the highest award (the great diploma of honor); while minor honorary diplomas were given to the Prussian War Office, to the city of Berlin, to the Bavarian Ministry of the Interior, to the city of Munich, to the Home Office and War Office of Saxony, and to other bureaux (government and municipal) of the Fatherland, as well as to Professors Salkowski, Kossel, and Brieger, of Berlin; Jaffé, of Königsberg; Kühne, of Heidelberg; Drechsel, of Bern; and C. Zeiss, of Jena. The gold medal was obtained by the Anilin-Fabrication Company of Berlin; by Schering, of Berlin; by Merck, of Darmstadt, and by two other German houses; while silver medals were literally showered on exhibitors of the same nationality for contributions to sanitary *matériel*. Among the recipients were professors in the various seats of learning throughout the Fatherland—Berlin in point of numbers heading the list. Italy, again, is well satisfied with the appreciation of her mineral waters embodied in the awards of the jury. On the court representing the Hydrological Department were the "Dean of French Hydrology," Professor Labat, of Paris, and the head of the German hydrological societies, Professor Winternitz, of Vienna, while Italian jurymen were the Senator Dr. Giulio Bizzozzero, Professor of General Pathology in the University of Turin, and Dr. David Borelli, Professor of Clinical Medicine in the University of Naples. Among mineral waters, Italian and foreign, the highest award was given to that of Fiuggi, which received the silver-gilt medal; silver medals were adjudged to Decref (Madrid) and Perrin (Vichy) for their waters; and the Giesshübl-Puchstein, the Franz Josef Bitterquelle, and the Tuscan Cinciano received bronze medals. Fiuggi, to which the place of honor has been assigned, is a water of great antiquity, which, like many good things Italian, has been allowed to fall into desuetude till now, when a vigorous effort is being made to reinstate it in the popularity it enjoyed in mediæval and classic times. Its source is in the Hernican country to the south of Rome, a beautiful tract of the Apennines celebrated by Virgil, and its efficacy in subjects of the uric diathesis is attested by clinicians of the stamp of Dr. Guido Baccelli, President of the Eleventh International Medical Congress, the Senator Dr. Mariano Semmola, Professor of Clinical Medicine in the University of Naples, and, indeed, by nearly every consultant of note throughout the peninsula. It ought certainly to be better known in this country, as its virtues, especially in gastro intestinal catarrh, notably, such as proceeds from uric and oxalic concretions, have been attested by British medical men practising in Italy.

M. Pasteur on Rabies.—M. Pasteur addressed the following reply to a lady who recently wrote to him for information respecting the symptoms of rabies: "M. Pasteur has had pleasure in receiving your letter of May 31st. The bite of a dog is only dangerous when the dog has got rabies. If there is any doubt in respect to this, the manner in which it may be found out is the following: Put the dog that has bitten where it can do no further harm. Have it examined by a vet., and if it has the rabies its characteristic symptoms will not be long of being observed, and the animal will certainly die in eight days. If at the end of that time no symptoms of rabies has been observed, the bite cannot cause hydrophobia, and there is no reason that the animal should be destroyed."

Attending Physicians and Consultation-fees.—An esteemed correspondent recently inquired:

"In consultations, is not the attending physician entitled to a consultation-fee in addition to his ordinary visiting-fee?"

We answered, "Yes."—*Medical News.*

All the same, the attending physician rarely gets it, and we see no particular reason why he should, though he might reasonably charge double his ordinary fee if much of his time is consumed.

Society Reports.

Congress of American Physicians and Surgeons.

Third Triennial Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from page 24.)

AMERICAN PHYSIOLOGICAL SOCIETY.

Seventh Annual Meeting, held in Washington, D.C., May 30 and 31, and June 1, 1894.

PRESIDENT HENRY P. BOWDITCH, M.D., OF BOSTON, MASS., IN THE CHAIR. WARREN P. LOMBARD, M.D., OF ANN ARBOR, MICH., SECRETARY.

FIRST DAY, WEDNESDAY, MAY 30TH.

A MOTION was made to appoint a committee of three to consider the advisability of publishing an *American Journal of Physiology*, and to report at the next meeting in December, 1894. Committee appointed by the president, consisting of Drs. Lee, Porter, and Donaldson.

Effect of Fatigue on the Rate of Transmission of Nervous Force.—DR. HENRY P. BOWDITCH, of Boston, read a paper with this title. The most important results obtained were by noticing the results of prolonged stimulation. Thus far there has been discovered no production of heat, nor chemical change, nor any great amount of fatigue produced by prolonged stimulation; shown in regard to the last point, for example, by the continuous action of the vagus on the heart; and, in sensory nerves, by long continued pain. But is there not some change?

The best understood phenomenon of nerve force or function is, perhaps, the rate of transmission, the generally accepted average of which is about thirty metres per second. Is the rate affected by prolonged stimulation?

The method used by Dr. Bowditch in his experiments was the nerve-muscle method. To use this effectually, there must be some method of "blocking" the current, or interrupting it between the nerve and the muscle, so as not to wear out the muscle. Of the various methods of doing this, by interrupting the current, by chemical action (*e.g.*, by action of atropia or curare on the muscle, or local application to the nerve, at point of entrance into the muscle, of ether), or by pressure (which latter Dr. Bowditch found entirely useless), he chose the use of ether, using a mixture of 20 parts of ether, 8 parts of six-per-cent. salt solution, and 2 parts of alcohol.

He found the current, or connection between the nerve and muscle, blocked after application for from one to six minutes; and on removal of the ether, the nerve recovered its conductivity in from two to four minutes. His first effort was to obtain an average effect on a number of different specimens, in order to compare with the normal.

He found, however, that there was a very wide range of results obtained by experimenting with frogs' nerves, and that the different nerves acted very differently. He showed by diagrams that the different effects showed a variation of from 10 to 15 metres up to from 45 to 53 metres, after use of ether or stimulation, or both, *i.e.*, in the lowest of his experiments the rate of the first nerve was 15 metres, and after use of ether or stimulation it was reduced to 10 metres; and in the highest case was 53 metres, afterward reduced to 43 metres per second.

In most cases the range of each individual experiment was not large, being from 5 to 10 metres; but in some was very large, being in one case from 20 to 40 metres per second. Dr. Bowditch had found a similar range in the experiments of other investigators, *e.g.*, in Helmholtz's a variation from 4 to 20 metres. He therefore feels that with the methods at present at our command, that we cannot hope to arrive at the true normal standard, the great variations depending upon conditions which we cannot control.

Dr. Bowditch conducted his experiments in the usual moist chamber, at a nearly uniform temperature. He found that rest did not affect the results, *i.e.*, the preparation did not deteriorate after keeping from one to three hours. In general he found that after use of ether alone the rate was somewhat lower than the generally accepted normal, viz., eighty-two per cent. of normal rate; that after stimulation it was slightly lower still; and after both, still lower, being about seventy-six per cent. of normal. But he considers the decrease comparatively slight; and that thus far he must conclude that prolonged stimulation, *i.e.*, fatigue, does not markedly affect the rate of transmission. He hopes to continue the investigation of this interesting question by photographic and electro-metrical methods.

The Physiological and Therapeutic Action of Nuclein.—DR. VICTOR C. VAUGHN, of Ann Arbor, read the paper. Physiologically nuclein may be said to form the chief chemical constituents of the lining parts of cells, the element by virtue of which the cell grows, develops, and reproduces itself. It is its function to utilize the pabulum within its reach. It is evident, then, that those tissues containing a large number of cells must contain the relatively largest amount of nuclein. It would also seem that it is by virtue of their nuclein that the different organs manifest their individual peculiarities and functions; and therefore that the nucleins from different sources would be very different, *e.g.*, that from yeast different from that from the spleen or the thyroid gland, etc., the number of kinds being limited only by the number of different cells.

It is the chemical basis of the nuclei of the cells, sometimes called by the histologists chromatin, from the ease with which it takes up staining materials. Chemically, the nucleins are proteid bodies containing a large amount of phosphorus, existing in the form of nucleinic acid, this acid being the same in all nucleins; but, combined with different bases gives us the different resulting nucleins. On reduction and recomposition they yield some of the so-called xanthin bodies. In general they are insoluble in dilute acids and soluble in dilute alkaloids, and resist peptic digestion.

Some substances histologically nucleins do not yield any xanthin base, and such are now called para-nucleins, and some of these are the antecedents of the true nucleins.

Some nucleins are combined with albumins forming nucleo albumins. Miescher was the first to study appreciatingly the nucleins, and was the one who named them.

He prepared his specimens for investigations from pus corpuscles, and later from the yolks of eggs.

In 1874 he made his most important contribution to the knowledge of nucleins by working with the spermatozoa of salmon. In a fresh state these were found to be very resistant to most chemical reagents, but were found to be destructively affected by dilute salt solutions (ten to fifteen per cent.).

The head of the spermatozoa was found to be practically free from albumin, and to consist of nuclein and small quantities of lecithin, cholesterine, and fat.

The nuclein molecule is wonderfully retentive of life, and possesses marked powers of self recuperation after being partly decomposed; as shown by the fact that after being partly decomposed by salt solution, if this solution be diluted by the addition of large quantities of water, the nuclein is restored to its original form and constitution.

Nuclein may be very markedly changed in chemical composition and functional powers, without changing its visible properties or form, which would readily account for the failure oftentimes to find, by macroscopical or microscopical examination, lesions distinctive enough or of sufficient character or extent to account for the severity of symptoms observed during life.

An artificial nuclein has been prepared by Lieben, which, however, is not a true nuclein, but a para-nuclein.

A close relation seems to exist between nuclein and uric acid, judging from the close relation of both to the xanthin bodies. Thus spleen nuclein when oxidized yields uric acid.

This origin of uric acid from nuclein will explain the origin of uric acid in the mammalian body, showing really the number of nucleated cells in the body which are being recomposed and not, as heretofore believed, being the result of imperfect oxidation of food stuffs, the complete product of which is urea.

Some of the nucleins have germicidal properties more powerful than corrosive sublimate. The germicidal constituent of the blood is nuclein, furnished by the polynuclear white corpuscles. Being thus germicidal can they be used to prevent or arrest the growth of germs in the animal body; and if so, in what manner do they act? Nuclein seems to be entirely non poisonous, large doses having been injected and administered by mouth in human beings with little or no unpleasant reaction. In some cases it caused a temporary elevation of temperature and a slight local reaction, but neither to any dangerous extent. He has used it in membranous tonsillitis, in streptococcus diphtheria, and in indolent ulcers; and in all cases with good effect. The action of nuclein in giving immunity from certain diseases is marked, as shown in some cases where it was used on rabbits, rendering them immune to the diplococcus pneumoniæ; but this is not due to its direct germicidal action, but to its power of stimulating some organ whose duty it is to protect the body against bacterial invasion.

Dr. Vaughn thinks that for immunity and cure of infectious diseases we must look for, 1st, Non-poisonous germides of cellular origin; and 2d, substances which stimulate the activity of those organs whose function it is to protect the body against those diseases. He thinks that nuclein fills both of these demands.

From the investigations of Dr. Huber he finds that, "1, The subcutaneous injection of nuclein increases the number of white blood corpuscles; 2, this increase occurs in both healthy and tuberculous persons; 3, the increase varies with the individual; 4, the increase is mostly in the polynuclear cells; 5, it generally appears within three hours, and disappears after forty-eight hours."

Action of Calcium on the Heart.—Dr. W. H. Howell then made an interesting demonstration of the effect of calcium salts on the contractility of the heart. He had the heart of a turtle in a bulb, connected with a very delicate water manometer; and having connection by a stop cock with three flasks containing: 1, Normal sheep's blood; 2, sheep's blood with the calcium salts precipitated by excess of sodium oxalate; and 3, sheep's blood with excess of calcium chloride. In the first instance the heart was fed with the normal blood, showing normal contractions; then it was fed with the decalcified blood, upon which the contractions became less frequent, the diastole being lengthened, and also irregular and jerky in its action, finally coming almost to a complete standstill, practically a potash paralysis. Then the blood with excess of calcium chloride was turned into the heart, which very soon began to beat more frequently and regularly and was finally restored to a practically normal condition.

Dr. Howell said it had been so far impossible to decide absolutely whether it was the absence of the calcium salts or the presence of the excess of the oxalates which caused the paralysis, it being at present practically impossible to precipitate all of the calcium salts without an excess of the oxalates. We cannot exactly neutralize the calcium salts, as we do not know in any particular sample of blood just how much is present in soluble and ergo precipitable form, and how much is in composition more or less stable with proteid and other bodies.

Ptyalinogen and Pexinogen.—Dr. J. W. Warren then made some remarks on the qualitative determination of ptyalinogen and pexinogen. The best way of determining the presence of pexinogen or the forerunner of the milk-curdling ferment was by chloroform water. Hammerstein, he said, had found pexinogen in nearly all animals; but in the mucous membrane of the ox it was not found, the pepsin being there already formed. Dr. Warren had found the opposite condition present in his experiments with the ox.

Ptyalinogen, the forerunner of the salivary ferment, ptyalin, he also determined by the chloroform-water method. He had found it present in almost every case excepting in the cat. The principal objection to the chloroform method was the difficulty of entirely removing the chloroform, and the fact that, if present, it gave a reaction with Trommer's test, simulating that of sugar. The quantity of ptyalinogen is small and yet it was always genuine. In some cases, of sheep and rabbits, he could get no results either for ptyalinogen, or for ptyalin itself in watery or chloroform-water extracts.

Dr. Warren used a one per-cent. solution of sodium fluoride, which acts as an excellent preservative of the different ferments of the body, and which does not reduce the reagents used for testing for sugar.

Ptyalinogen is not very soluble as compared with the forerunners of the other ferments of the body; and is apparently not so stable and permanent. No result was considered satisfactory nor reported where the action did not appear within one hour.

Chemistry of Muscle.—Dr. G. N. Stewart then read a paper on this subject. He stated that his first experiments had been to get information as to whether the proteid substances usually said to be present in muscle tissue, and which had all been derived chemically from dead muscle, existed as such in living muscle.

He differed from and criticised Halliburton's theories, as to the presence of myosinogen in the muscle tissue, and the fact of its clotting to produce the rigor mortis; and also criticised Halliburton's conclusions from his method of practical precipitation of the proteid borders of muscle tissue.

Following, however, Halliburton's methods to a certain extent, he found the quantities of myosinogin and the other proteids quite different in the different muscles of the body; *e.g.*, those in heart muscle different from those in the skeletal muscles and some differences in the different groups of the skeletal muscles; the larger percentages of easily coagulable proteids being as a rule in the more active and more easily irritated muscles. The rigor mortis being different in different muscles, are not the extracts of the different muscles also different in the quantities and coagulability of their proteids and is the myosinogen of one different from that of another? Dr. Stewart thinks that such differences do exist.

In a series of experiments on fifty frogs' hearts and skeletal muscles he found slight difference in the temperature at which the proteids of these heart-muscles coagulated and that at which proteids from skeletal muscles from the same frogs coagulated.

In the case of rabbits' hearts he found the same result. Also by direct application of heat to the muscles, it needed a higher temperature to cause a "rigor mortis" in the heart than in the skeletal muscles.

In the following tables, which illustrate these results:

I. Is the percentage precipitate occurring between 47° and 49° C.
II. Between 56° and 58° C.
III. Up to 65° C.
IV. The balance of coagulable proteid with boiling.

Also according to Halliburton's results of fractional precipitation and his nomenclature:

I. Is para myosinogin.
II. Is myosinogin.
III. Is myoglobulin.
IV. Is serum albumin.

Halliburton claimed that para-myosinogin did not clot; but according to the fractional precipitative method Dr. Stewart found it present in muscle clot in large quantity, and therefore judges it essential to the formation of the clot, and fully as much so as myosinogen.

These tables show percentage of different proteids, as

per above explanation, in the heart and skeletal muscles of a rabbit:

	Heart. Per cent.	Skeletal. Per cent.
I.	76.1	70.9
II.	Slight	19.7
III.	"	Slight
IV.	23.9	9.41

In one experiment Dr. Stewart heated a muscle from a cat's leg at 42° C. for ten hours. Then made extract of it, and found that all the proteids excepting serum albumin were precipitated at about 42° C., showing that the rigor mortis (thus artificially produced) causes some change in the muscle proteids, if Halliburton's method of fractional precipitation, as precipitating pure chemical bodies, be accepted.

In another case Dr. Stewart prevented rigor mortis of a muscle by pressure, and then upon making extract and comparing it with results from a muscle in which rigor mortis had taken place found very little difference between the two, as will be seen from the following table. "A" being the one in which rigor mortis had taken place; "B" being the one in which it had been prevented:

	A. Per cent.	B. Per cent.
I.	70.	68.2
II.	21.4	24.8
III.	8.7	6.9

He thought that, theoretically, if muscle were examined after rigor mortis had passed off, there should be found a difference in clotting power as compared with muscle examined before rigor mortis; but had not found it so.

Dr. Stewart concluded that the methods at present available for investigation of this subject were incomplete and faulty and hoped for better ones soon.

Second Day, Thursday, May 31st.

Circulation Time in Organs.—Dr. G. N. Stewart, of Harvard University, read the paper. As to method, it was necessary to cause some condition of the blood which could be easily noted, would disappear quickly, and which would admit of new and repeated observations.

Of various possible methods, Dr. Stewart used that of injecting a quantity of salt solution into an afferent vessel, and then determining, by the difference in conductivity of an electric current, caused by the presence of the salt in the blood, the time at which the salt solution had reached the efferent vessel, thus giving the time of circulation through the organ. The electrodes may be placed upon the vessel, and do not need to be inserted into the vessel nor into the blood-current.

He found the time of circulation longest in the kidney (occasionally about as long in the spleen), the average of many experiments being 11.58 seconds. The pulmonary circulation time he found the shortest of any organ in the body (excepting sometimes the coronary circulation), being from two to four seconds It was also more constant than that of any other organ, and might well be used as a sort of unit or standard.

The liver circulation was from four to seven seconds; the thyroid gland, five to six seconds, and capable of reduction by section of the cervical sympathetic; in the spleen the average time was 10.95 seconds. In one case, using an animal which had been used previously to demonstrate the motor areas, and which had spasms during his observation of the pulmonary circulation, he found that time much shorter.

In another case, where an overdose of chloral had been given, he also found the time much reduced, probably due to the marked dilatation of the whole vascular system. For measuring the circulation time in the intestines and the coronary vessels, Dr. Stewart used the method of pigment injections, using two per cent. solution of methylene blue. In the intestines the time was a trifle longer than the lungs, and about one-third as long as in the liver. The coronary time was short, being about three seconds, very little, if any, change being caused by stimulation of the vagus; if any change, it was a decrease of time, not an increase.

Dr. Stewart claimed that the results were not affected, as some had claimed, by the diffusion of the salt solution, as the time during which any one observation was made was not long enough for any appreciable diffusion to take place.

Some Experiments upon Reflex Vaso-constriction and Vaso dilatation.—Dr. W. H. Howell sent a paper with this title, which was read by Mr. R. Hunt. The object of the experiments was to study the conditions under which a reflex fall of the general blood-pressure can be obtained.

If chloral be administered to a rabbit, and the central end of the cut sciatic nerve be stimulated, a fall of pressure occurs, instead of the usual rise.

It is generally held that the sensory nerves contain both pressor and depressor fibres, and that upon fatigue of the vaso-motor centres they are more influenced by the depressor than by the pressor fibres.

Recently Kleen described that a pure muscular stimulation, as by kneading a muscle, caused a fall; whereas a cutaneous stimulation caused a rise of pressure.

Dr. Hamell also has shown that, by cooling the sciatic and stimulating the nerve peripherally to the cooled portion, a fall was caused, which was followed by a rise if the nerve were warmed and again stimulated.

Dr. Howell and Mr. Hunt found that when the nerve was cooled that anæsthesia had a marked effect upon the pressure under anæsthesia, caused by pressure on the cerebrum, in cats, the vagi being cut; mild stimulation of the sciatic at the temperature of the room caused a marked rise of pressure. At 10° C. the same stimulation caused a fall, while at the same temperature a strong stimulation caused a rise of pressure.

At 5° C. both strong and weak stimulation caused a fall. At 15° both strong and weak stimulation caused a rise. The change from a fall to a rise was often very rapid after changes of the temperature.

Ether, alone or with other anæsthetics, seemed to have a marked influence in bringing out the depressor effects; under ether a rise was usually caused by moderate stimulation at the temperature of the room, but a fall at lower temperatures. Curare seemed to have an opposite effect to that of ether, *i.e.*, bringing out more prominently the pressor effects. At low temperatures no fall could be obtained in the curarized rabbit, and at higher temperatures the rise was very marked.

Under acetone chloroform the vaso-motor centres seemed to be not very irritable and the changes in pressure not great. Upon rhythmical stimulation under pressure anæsthesia, only a rise was obtained varying directly with the strength and rapidity of the stimuli. Local application of drugs to the nerve had little or no effect, excepting that some, *e.g.*, ether, completely blocked the impulses.

The cause of the above effects cannot yet be fully answered. Dr. Hamell's method seems good evidence of the existence of two sets of fibres, pressor and depressor, the conductivity of the former being more quickly diminished than the latter by local causes. When drugs are injected into the circulation, probably, or perhaps, the centres themselves are affected.

Brain Centres of the Bladder.—Dr. Isaac Ott, of Easton, Pa., gave the results of a few preliminary experiments on the cerebral centres of the bladder. Previous experimenters had noted that electrical stimulation to the corpora quadrigemina caused a contraction of the bladder. Dr. Ott found that, on cross section of the crura cerebri, a flow of urine followed; also that when the surface of the exposed crura was touched the bladder contracted. If small doses of atropia were administered he still got contraction, but failed to get any after large doses, *e.g.*, gr. ij. of atropine sulphate in an ordinary sized

adult cat. He used only mechanical stimulation. His conclusion was that the centre or centres lie in the crura cerebri, the exact portion of the crura, however, being not yet determined.

Volume Changes in Muscle during Activity and Rest.—Dr. G W. Fitz, of Harvard University, read a paper with this title. He used a plethysmograph on the arm, with indicators giving tracings showing the rapidity, length, and force of the contractions of the muscles, the pulse-beat, and the changes in volume. He found changes in both pulse and volume, but directed attention particularly to the changes in volume. On contraction of the muscles, *i.e.*, in state of activity, the volume was markedly diminished, in quantity varying, in different arms and in different experiments, from 20 to 75 c.c.

He found the crura indicated by the plethysmograph quite different when repeated contractions were rapidly made, as in the milking motion, from that where there was a single long-sustained contraction.

In the stage of fatigue there was a large variation in the volume of the arm, a marked filling up, or increase of volume. With each arm of same patient in a plethysmograph, one exercising and the other quiet, there were slight effects noted in the quiet arm as well as the marked changes in the active one.

The time taken to get the maximum effect was from fifteen to twenty seconds, and a similar time was taken for the arm to refill. These changes, Dr. Fitz claims, are changes in the quantity of fluid in the arm, probably entirely in the amount of blood in the vessels, the quantity of lymph in the lymphatic spaces not being much affected, as the time necessary to cause the change is so short. Also when the shape and relative bulk of the muscles are considered, and the relatively small amount of other tissues in the arm, it seems likely that the change is limited to the muscles.

By the contraction of the muscles the blood is squeezed out of the vessels, both arteries and veins; and there is thus a change in volume and an anæmia of the arm, because for the time being the blood pressure is not enough to overcome the force of contraction of the muscles. When, however, the muscle becomes fatigued, the blood can force itself into the vessels, causing an increase in volume, and a congestion of the arm.

Dr. William H. Howell, of Johns Hopkins University, exhibited some very interesting "plethysmographic curves taken during sleep." He found the arm congested during sleep, and contracted or anæmic during waking; and, taking account of the already known theory of the absence of vaso-motor control in the brain, the quantity of blood there depending upon the condition of the circulation of the other parts of the body, and varying inversely as the quantity in other parts, he brought out a very suggestive indication from the curves, of the probable parallelism between the amount of blood in the brain and the condition and intensity of consciousness.

Upon stimulation of any of the centres, *e.g.*, the auditory centre by any noise, the person experimented upon being asleep, the arm became anæmic, indicating a corresponding congestion of the brain, this change being in direct proportion to the strength of the stimulus.

These experiments led Dr. Howell to suggest a possible theory as to the cause of sleep, viz., that the anæmia known to exist in the brain during sleep, and which has so far been considered to be a secondary condition, is really the cause of sleep. The explanation offered was that the circulation of the brain, or the amount of blood, varies inversely to that of the balance of the body; the vaso-constrictor centre is in a condition of tonic activity during waking, thus keeping the quantity of blood reduced in the body and increased in the brain; this centre becoming fatigued, the body vessels dilate and fill up, those of the brain empty themselves, and when a certain level is reached sleep ensues.

The Cardiac Pleurogram.—Dr. S. J. Meltzer, of New York, read a paper on "The Cardiac Pleurogram and the Nature of the Cardio-pneumatic Movements." If a manometer or other recording apparatus be connected with the mouth, nose, or trachea, while respiration is suspended, respiratory oscillations can be observed coinciding in time with the cardiac movements.

These were explained by Voit in this way: During systole an inflow of air into the lungs occurs to counterbalance the effect of the diminution in size of the heart; the opposite occurring in diastole. Later Ceradini recognized the fact that the change in pressure could not take place as long as the blood thrown out by the heart remained in the thoracic cavity; but it is only when it is leaving the thoracic cavity that the respiratory movement occurs. Therefore the cardio-pneumatic undulations are due not to change in size of the heart, but to change in the quantity of blood within the thorax.

Landois found a short but distinct expiration preceding the main inspiratory movement, and after this main movement two more small respiratory undulations occurred before the new cycle commenced. Registration of the respiratory undulations may also be made by means of apparatus placed in the œsophagus, as done by Martins and by Dr. Meltzer. Many tracings were obtained of the cardiac movements, to which Dr. Meltzer gave the name of cardio-mediostinograms. The distinctness of these tracings seems to depend upon the depth in the œsophagus at which they were taken, least distinct in the cervical region, sharp and clear in the thoracic portion, excepting in the immediate vicinity of the diaphragm, where they were sometimes wholly absent. The results showed the same general fact, viz., an inspiration at the systole, an expiration at diastole of the heart.

Dr. Meltzer showed a number of tracings taken by the œsophageal method, showing the curves of the cardio-respiratory movements very distinctly. In general, in dogs, in each cardiac cycle there appeared a steep systolic down-stroke, followed by a gradually ascending diastolic line with some fine oscillations, showing that during systole the pressure is suddenly lowered, and during diastole gradually returns to its former level. This, as in all the œsophageal-cardiac tracings from the dog, showed a so-called negative pulse.

In experiments on himself Dr. Meltzer found also a negative pulse in the œsophagus down to twelve centimetres from the beginning of the œsophagus; below fourteen centimetres the pulse was positive, showing an up stroke of the indicating lever, or an expiratory movement.

Dr. Meltzer referred to Haycraft and Edie's experiments, from which they claimed that the cardio-respiratory movements disappeared upon lifting the heart away from contact with the lungs, and that the lungs really acted as an oncometer placed about the heart, and that the air in them is affected by the cardiac impulse just as the air in a cardiograph placed against the chest.

To test this explanation Dr. Meltzer made tracings of the cardiac movements directly from the pleural cavity, calling them cardio-pleurograms.

From these he obtained in general the same results as before, with slight modifications due to the different conditions and methods, and therefore argues that since both heart and lungs were far from the openings leading to the tambour, the movements are not due to the lungs acting as an oncometer for the heart, and that they are due, as at first stated, to the change in the quantity of blood in the thoracic cavity.

Dr. Meltzer thought that Haycraft and Edie's results were perhaps due to their method of opening the chest, which caused a very abnormal condition with relation to its surroundings. In rabbits free access of air to the chest cavity caused the cardio-respiratory movements to disappear; in dogs they were diminished, but did not disappear. This, Dr. Meltzer thought, depended upon the different arrangement of the organs in the posterior mediastinal space, in rabbits and in dogs. His conclusion was that these cardio-respiratory movements were nor-

mal, and undoubtedly caused, as above stated, by the changes in the quantity of blood within the thoracic cavity.

THIRD DAY, FRIDAY, JUNE 1ST.

Reflex Time of Winking.—DR. W. P. LOMBARD, of Johns Hopkins University, read a preliminary report of experiments to determine this point. He used a very ingenious apparatus for producing the stimulus—a plunger, worked by electricity, striking the cheek about one inch from the outer canthus of the eye, the stimulation being mechanical. An electric current is broken at the blow of the plunger, and immediately closed by a spring, and again broken by the movement of the eyelid in winking; the time between the two breaks being measured gives the time of winking. Tracings were taken on a drum, of the stimulus and the wink, and parallel with these, of the vibrations of a tuning-fork, of known rapidity of vibration.

The time varied somewhat in different persons, and in the same person at different times; but in general was a little shorter than that determined by previous experiments, being about 0.04 second. If from this be subtracted the time of transmission and the latent period of the muscles, the time will be probably reduced to about 0.03 second.

An Improved Hæmatocrit.—DR. JUDSON DALAND, of Philadelphia, showed, by request, his improved hæmatocrit, for examination of the blood by the centrifugal method. He claimed for it, as advantages over the instruments at present in use, its greater compactness, higher speed of revolution of the frame or spindle carrying the capillary tube; the shorter length of the tube, and its lens face, making the reading easier; the new scale, reading the normal amount of corpuscles in the blood as one hundred per cent.; and the fact that by it the blood could be used in its normal condition direct from the circulation without dilution.

A Short-circuiting Commutator.—DR. W. P. LOMBARD, of Johns Hopkins University, showed an ingenious and very simple short-circuiting commutator, affording, making, or breaking induction shocks.

It consisted of two hard-rubber wheels or disks, set on a brass shaft, and having in the circumference of each a brass plate connecting by contact with the shaft. One of these wheels rotates on the shaft. Against these wheels the usual brush rests, and by rotating one of the wheels upon the shaft the current of the short circuit can be made to precede, or follow, the primary current at will.

The device can easily be attached to any apparatus.

Dr. Lombard also showed an improved hand-rest for use with the ergograph, whereby the usual variations caused by the unconscious and involuntary withdrawal of the hand and arm from the ordinary hand-rest, and the use of other muscles than the particular one desired, can be avoided.

He also showed a "non-oxidizable mercury key," consisting of a hermetically sealed "U" tube in two parts, a segment of rubber tubing connecting the two parts; the tube is partly filled with mercury, the balance being filled with nitrogen (for which may be substituted hydrogen or other non-oxidizing gas), no air being in contact with the surface of the mercury; into each end of the tube is soldered a platinum wire; and pressure on the rubber segment of the apparatus causes the column of mercury to come into contact with the wire at one end of the tube, thus completing the circuit; on relaxation of the pressure on the rubber tube the mercury falls of its own weight away from the wire, thus breaking the circuit.

Anæsthesia by Cerebral Pressure.—DR. G. T. KEMP, of Johns Hopkins University, read a paper on this subject. Of the various methods for producing pressure, *e.g.*, injections into the subdural space, direct pressure after trephining with blunt instruments, the air-bag, etc., he used a thin rubber bag inserted through a cannula, which is put into a trephine hole, and distended this with salt solution.

His object was to find if the production of anæsthesia was practical and practicable, especially when anæsthesia by other means was contra-indicated, as in long-continued laboratory experiments on animals, or where it was desirable to avoid, in any particular experiment, the effects, other than anæsthesia, produced by the drugs ordinarily used for that purpose.

He used chloroform for the primary operation of trephining and applying the pressure apparatus, then allowing the effects of the chloroform to pass off, noted the effects of the cerebral pressure. The effects of slight pressure were pain and stimulation, especially of the medullary centres.

All these centres were stimulated early, and this was followed by exhaustion, and later still by paralysis. The vagus centres responded first, and respiratory centres became exhausted first. He found that it was the automaticity of the centres that was exhausted, and not the centres themselves; as after the suspension of their automatic action they still responded promptly and vigorously to any direct stimulation. He found that he could not use pressure enough to cause complete anæsthesia without doing some damage to the medullary centres, this fact being probably due to the anæmia of the medulla caused by the pressure.

He concluded, however, that for many experiments it was a means of causing anæsthesia that was of great practical value for laboratory work.

He exhibited a number of beautiful tracings showing the results in several experiments, some of them of several hours' duration, with the curves of the respiration, blood pressure, and the artificial cerebral pressure.

Respiratory Paths in the Cord.—DR. W. T. PORTER presented a paper with this title. He noted Rosenthal's work on the automatism of the respiratory centre, and the fact that the exact location of the centre had not yet been determined. He showed, however, by the fact that, although some irregular movements of the diaphragm take place after separation of the cord from the medulla, no full, regular, respiratory movements occur, that there is no automatism in the cord so far as respiration is concerned.

He then detailed many experiments made to trace the path or paths of respiratory impulses from the centre through the cord.

His first experiment was to make a hemi-section of the cord on one side at the level of the second cervical vertebra; then a hemi-section on the other side at the level of the point of the calamus scriptorius, of all excepting a very small portion of the outer part of the lateral tract.

Breathing stopped at once, but after a few minutes of artificial respiration the breathing began again and continued.

Later the remainder of the lateral tract was cut, and then breathing stopped again and could not be restored by artificial respiration, showing that the respiratory impulses descend in the lateral tracts, and that they do not cross between the two points above mentioned, at which the sections were made.

Dr. Porter detailed many more experiments similarly carefully made; and as to the place of crossing, suggested in general three possible solutions, viz., the crossing occurs between the bulb and the phrenic centre, or at the level of the phrenic centre, or by no definite path, but diffusely, anywhere.

From his experiments, which were too great in number to give in detail, he deduced the conclusion that the respiratory impulses pass down the cord through the outer part of the lateral tracts; that they can and do cross on their way down without dyspnœa; that they do not cross diffusely in any and all parts of the cord; that they do not cross between the level of the bulb and that of the phrenic nuclei; that they do cross at or about the level of the phrenic nuclei, viz., in the region of the fourth cervical vertebra.

He further suggests the following interesting hypothesis: That the fibres descending in the lateral tracts and

transmitting the respiratory impulses end at the level of the phrenic nuclei in arborizations; that each phrenic motor cell has two sets, or two sorts, of branches, the axis cylinder and the protoplasmic or dendritic processes; that the latter have two distributions, some, the greater part, end on the same side, the others cross to the other side of the cord, and both come into contact with the end arborizations of the fibres from the respiratory centres. Thus the end arborizations of each respiratory fibre are in contact with phrenic cells of both sides. That ordinarily the impulses will follow the path where there are the greater number of processes or dendrites; but that if this part be disturbed or obstructed or cut off, they then can take the other one; crossing to the other side of the cord and following down the phrenic of that side.

Dr. Porter claims that the only point of this hypothesis which does not rest upon established anatomical, histological, and physiological facts, is the relation of transmission to the number of dendrites.

Action of Strychnine on the Cord.—Dr. A. R. Cushing read a paper with the title "Some Facts Bearing on the Action of Strychnine on the Spinal Cord."

He claimed that there is a coincident paralysis and stimulation of strychnine-poisoning.

His method of procedure was to expose only a part of the cord to the action of strychnine at a time.

He first applied strychnine about the branches of the brachial plexus. The usual tetanic condition resulted; but he found that, although if the upper extremities or upper part of the body were touched the usual tetanic spasm followed; if only the lower limbs were irritated there was no response at all, or only a feeble one.

After a few minutes he could obtain the full results from touching the lower limbs, owing to the fact that the strychnine had spread down the cord. When the reverse experiment was tried, *i.e.*, the lower part of cord exposed to strychnine, the upper part being protected, the results were similar; *i.e.*, a full response from irritation of lower extremities and none from the upper, until after some time had elapsed, and the strychnine had diffused through the whole cord. He concluded that in order to produce strychnine tetanus it was not necessary to apply strychnine to the motor cell itself; that strychnine acts chiefly upon sensory cells; and that the chief resistance to strychnine lies in the sensory cells.

The Society then adjourned, to meet in Baltimore in December of this year.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Sixteenth Annual Meeting, held in Washington, D. C., May 30, 31, and June 1, 1894.

(Continued from page 24.)

SECOND DAY, THURSDAY, MAY 31ST.

Results of Cutting Operations in the Nasal Septum was the first paper of the session. Dr. Thomas R. French, of Brooklyn, directed especial attention to perforation of the septum and membranous adhesions occurring as a result of operations on the nasal septum.

In reperforation he said that as the methods generally employed to correct deviation of the septum were not always successful, he wished to present for discussion a question which had often arisen in his mind, viz.: If a successful result cannot be obtained in any other way, are there not conditions under which perforation of the cartilaginous septum can be made a perfectly justifiable procedure?

From his study of the result of perforation made by others, and from his own and other experiences with perforations with unhealed edges, he expresses his belief that, with proper care in the after-treatment, perforation can be deliberately made without injury and with great relief in a certain class of cases; that if the breath-way through the obstructed side cannot be obtained without leaving a hole in the septum, such a procedure is justifiable if the patient can be impressed with the necessity of leaving the parts alone, and it is reasonably certain that the case can be carefully followed until healing of the edges has occurred; otherwise it is an unjustifiable method of operating.

He, however, excepts from that statement the perforations made near the entrance of the nostrils, particularly in a septum bent obliquely across both openings, by the Blandin punch.

In re membranous adhesions, after reviewing the recognized causes of this annoying sequel of operations within the nasal passages, the author called attention to a cause, heretofore overlooked, viz., that cut surfaces on the septum will become adherent to scar-tissue on the turbinates made by the galvano-cautery at some previous time. Therefore, in patients who present for treatment whose nares have never been subjected to operative procedures, and in whom there is need of the destruction of turbinated tissue and removal of obstructing cartilage or bone, the septum should be operated upon first, when, after a month or more has elapsed, and it is certain that the mucous membrane is completely reformed, the turbinates can be safely destroyed by any method. When, however, patients object to a cutting operation on the septum, but are willing to submit to the destruction or removal of turbinated hypertrophy, preference should be given to the use of the snare or acids in order to avoid the possibility of leaving a surface which might become adherent to a wound opposite in the event of a cutting operation on the septum being performed later.

Without doubt adhesions are frequently occasioned by saws with unprotected ends, and the unskilful use of trephines and cutting forceps in narrow passages. A distinct advance will be made when all instruments used for septal operations are constructed with a view to preventing the possibility of wounding the outer wall of the nose.

It is a good rule, in operating with the saw, to begin the section by cutting upward, and finish it by cutting downward. But whether it is begun from above or below, the section should be finished by a cut from the opposite direction; for in this way the maximum amount of tissue can be removed from the septum with the least danger of injury being done to the outer wall.

Dr. J. H. Bosworth, of New York, said that he had been credited with having said that he had only had one perforation of the septum from the use of the saw. What he did say, however, was that, up to the completion of his first 169 cases he had had only one perforation, but had had many since. A perforation in the antero posterior direction is practically harmless; but if it is so shaped that it presents a projecting edge or angle to the current of air, it is harmful.

Dr. John O. Roe, of Rochester, did not believe that with perforations in adults there was danger of a falling in of the nose, but there is a real danger thereof in children. Perforation from operation is bad surgery. We cut through what we should cut away. He believed that the septal forceps devised by him would prevent this accident, as, by means of a screw in its handle limiting the approximation of the blades, this was prevented. The intact mucous membrane on the non-diseased side acts as a splint to help support the septal fragments till healing occurs.

Dr. William H. Daly, of Pittsburg, said that perforation should be mentioned only to be condemned. These cases don't stay cured. Many minor factors may conduce to septal deviation, such as lying on one side, the use of the handkerchief, etc. He had had poor results from Roberts's "pin operation."

Dr. C. M. Shields thought that the thickening found in these cases was nature's protection against further bending. Removal relieves the symptoms, but nature reproduces the deformity. He prefers the knife as the *puret communites*. He makes parallel antero-posterior incisions above the line of deflection and joins them by a perpendicular cut over the salient angle. He has seen perforation result therefrom.

Dr. W. E. Casselberry, of Chicago, would object to

perforation on æsthetic grounds. We need not worry where the condition results from accident. He could not accept Dr. French's view, that adhesions result only where there is a solution of continuity on both of the opposing surfaces. Naso pharyngeal tumors often form adhesions from mere pressure on surrounding surfaces. Furthermore, as to hemorrhage from the septum: it does come at times from the cut surfaces, and not from injuries to the turbinated bones.

Dr. M. J. Asch alluded to the operation devised by him and presented to the association a few years ago. Few failures had resulted therefrom.

Dr. J. W. Gleitsman, of New York, said that the failure to relieve the symptoms in many of these cases arose from the fact that, back of the septal deformity, there is frequently an enlargement of the inferior turbinates. The latter may swell up in the air, rarefied by the septal obstruction.

Dr. S. W. Langmaid, of Boston, asserted that our operations ought to leave the patient in better condition than the one in which we found him. Adhesions have frequently resulted from caustics, which produced corrosive action, followed by granulation-tissue. Operation should never be undertaken unless we can keep a careful watch on the patient until healing has occurred.

Dr. W. Peyer Porcher, of Charleston, had seen severe hemorrhage follow the breaking up of adhesions. He thought iodoform gauze incomparably the best material for tamponing in these cases.

Dr. M. R. Brown, of Chicago, believed that bleeding in septal operations sometimes came from an injured turbinate; not always, however, as the septum may bleed furiously. He has never found it necessary to perforate the septum intentionally but twice, and did it far back from the concave to the convex side.

Early Operation in the Diseases of the Antrum of Highmore.—Dr. W. H. Daly, of Pittsburg, advocated an exploratory opening for purposes of diagnosis, and had treated twenty-seven cases since 1882. It was possible to teach the patients to irrigate the sinuses by taking water into the mouth, and then, by a sort of bucco-lingual compression, force the fluid through the opening into the antrum, so that it would rinse out the latter and escape through the nose. As the proper site for opening, he advocates a point just above the second bicuspid tooth of the size of a small goose quill. Davidson's syringe, with a small tube nozzle of proper curve, makes the best irrigator. Partitions in the antrum should be broken down. A conical burr-head drill makes the best perforator.

After operations constitutional symptoms may develop. Pain in these cases is often referred to a point above the eye. In regard to the site of operation, he finds in many instances a resiliency of the antrum wall just at this point. The cheek will cover the opening, but not always prevent the entrance of particles of food.

Dr. A. W. de Roaldes, of New Orleans, said that he had found but little difficulty in washing out the antrum through the natural opening. If an artificial one was necessary, it should be relatively large.

Dr. Brown preferred to make the opening low down between the roots of the teeth, and thus go through a portion of the alveolus itself. Thereby we enter the antrum through the floor. We may enlarge the opening, if necessary. We should remove the drainage-tube early, as its prolonged use keeps up the discharge. Irrigation through the natural opening is feasible, but tiresome.

Dr. J. H. Bryan, of Washington, made a plea for conservative surgery on this cavity. A diagnostic opening could be made through the middle or inferior meatus, according to the method of Moritz Schmidt. Duration of the case depends on its past history. For irrigation only the mildest solutions should be used.

Dr. Schields had often found that the discharge would cease after the tube was removed. The opening will always close up when the patient is syphilitic.

Dr. Casselberry believed that antrum disease rarely exists alone. Other cavities are also affected at the same time. These latter suppurate, and so prolong the case. Hence, even drainage of the maxillary sinus can never cure these cases. The pain above the eye, mentioned by Dr. Daly, may come from coexisting disease.

Follicular Odontoma Invading the Antrum of Highmore.—Dr. A. W. de Roaldes, of New Orleans, read a paper, entitled "A Case of Compound Follicular Odontoma Invading the Right Antrum of Highmore and Obstructing the Corresponding Nasal Fossa, with a New Apparatus for Administering Anæsthetics, especially Adapted to Operations on the Mouth, Nose, and Throat." He said that cases of that kind were so rare, and our American literature so barren on this topic, that every one deserved to be made public.

The condensed history of the case is as follows:

Young Daniel A——, an otherwise healthy boy, aged nine, was first seen by Drs. Guice and Rembert, of Natchez, in July, 1892. His right upper jaw presented two points of disease—one a fibrous growth occupying the socket of the central incisor tooth, and the other a hard osseous tumor, covering a considerable portion of the palatal bone back of the missing canine tooth, extending posteriorly alongside the internal plate of the alveoli to near the tuberosity of the maxilla. Both growths were removed, but in the spring of 1893 the osseous tumor had returned, when it was operated upon again during the summer. A short while after necrosis of the bone was found at the seat of operation, and the antrum was found exposed.

When examined by Dr. de Roaldes, a hard bony tumor was found occupying the right cheek, depressing the vault of the palate, and encroaching upon the right nasal fossa, fused with the alveolar border, especially at a point corresponding with the missing canine tooth.

A diagnosis of benign neoplasm was made, probably an osteoma, but with a possibility of an odontoma; this recorded point to be cleared by previous history, as to eruption of teeth, which history was unobtainable at the time. A radical surgical procedure was advised, and was performed March 4, 1894, by a modified Vollet's operation; the whole anterior wall of the antrum was removed from nose to tuberosity, from alveolar border to orbital floor, and main mass of obstructed growth chiselled out from place corresponding to canine fossa. On its surface were tufts of hard adherent tissue; a large number of smaller masses, to the number of fifty or more, some of them tooth shaped, were gouged out in all directions. After thorough curettage, cavity was packed, parts nicely sutured and bandaged. Patient made rapid recovery, and returned home March 23d; and, twelve weeks after, cavity is two-thirds filled, and photographs show scarcely any disfigurement. Microscopical examination, made by Dr. Borden, U. S. A., shows tumor to consist, as shown in micro-photograph and drawing of pathological specimen presented, of hypertrophic tooth capsule, which ossified sporadically in places, producing a number of denticles (50), which had originally probably all been bound together by periosteum, the denticles being embedded in the fibro-vascular structure, much as plums are in a plum pudding. The denticles consist entirely of cementum, and the origin of the tumor was connected with the unerupted canine tooth. No dentine or enamel tissue could be found in the specimen. The case, a very interesting one, resembles closely those of Sims, Bellander, and Mathias, figured in Sutton's work.

The points of interest brought out by the case reported by Dr. de Roaldes, and on which he insisted, were: 1. The rare character of the tumor, which contained, as far as he knows, the largest number of denticles. 2. Its very uncommon origin in an unerupted canine tooth. 3. Its location in the upper maxilla, and, as the above-mentioned cases, on the right side. 4. Its coexistence at one time with another fibrous tumor developed in the alveola of the right upper central incisor, probably itself a fibrous odontoma. 5. The fact that odontomata have often been taken for exostoses, fibroid tumors, etc. 6. The difficulty of the diagnosis, especially when growth is

embedded in the maxilla. The consideration of the duration of the disease, the age of the patient, and especially the absence of one or more teeth, will help to ensure a precise diagnosis. 7. The propriety of avoiding in those cases dangerous operations, as has been often done, in removing the maxilla, when proper chiselling and enucleation will generally suffice.

Dr. A. W. de Roaldes concluded by presenting, in the name of Professor Souchon, a new apparatus, devised by him for administering anæsthetics, and which had been of great service in the present case.

Cockle-Burr in the Larynx.—Dr. Charles M. Shields, of Richmond, reported an extraction of a cockle-burr from the larynx. The patient, a farmer from Halifax Co., Va., had observed one of his hogs being chased by some dogs. He rode after them until the bushes prevented farther pursuit on horseback, and, dismounting, he continued the chase on foot. This exertion made him breathe rapidly through the mouth, and he was suddenly stopped by feeling that he had drawn something into his throat that prevented easy breathing.

The foreign body was found to be a burr lying in the glottic space at its anterior commissure and just at the lower level of the cords. Its long axis was lying anteroposteriorly, and it was fastened firmly in position by the closing of the glottis on its spurs. It had been grasped just in the act of passing through. The patient had a most sensitive throat, and manipulation was thereby rendered more difficult. After being sprayed with cocaine, Mackenzie's and other forceps, opening laterally, were repeatedly tried without success, because of the inability of getting the blades between the burr and the bands on either side to which it was so closely adherent. Then a wire loop through a curved cannula was likewise unsuccessfully tried, the rapidly contracting vocal bands flattening the loop. Cotton twisted on a curved probe, with the hope of engaging the prickles in its meshes, met with no better success, and a curved blunt curette passed below the burr failed to extract it on being withdrawn.

Just before doing a tracheotomy, which had now been decided on, Schrötter tube forceps were again tried. This time, after pushing them between the cords closed, they were forcibly opened as the cords tightened on them, and, being drawn forward, the blades slipped over the burr, which was withdrawn entire.

Laryngeal Neoplasms.—Dr. Charles H. Knight, of New York, reported three cases of this nature:

Case I. *Diffuse Subglottic Myxoma.*—Partial removal by the mouth with Mackenzie's forceps. Tracheotomy under cocaine and radical extirpation of the growth through the wound. Recovery without a bad symptom. No recurrence.

Case II. *Papilloma of the Larynx.*—Removal with Mackenzie's and the Schrötter Türck forceps. Electric cauterization of the base of a growth attached beneath the right vocal band. Restoration of voice within three weeks, complete aphonia having existed for nearly eight months.

Case III. *Multiple Papilloma of the Larynx.*—Removal with Mackenzie's forceps. Recurrence and removal in twelve months. Second recurrence and removal in a similar way five years later.

Dr. Arthur O. Bliss, of Philadelphia, reported two cases of malignant tumors of the larynx.

Case I. *Squamous Epithelioma of the Larynx.*—Patient, male, aged forty-six, with negative previous history. Had been growing hoarse the past two years. Had gradually increasing difficulty in respiration and enlarged glands. Refused radical operation. Trachea opened through two upper rings. Heart sounds suggested atheroma. Considerable albuminuria, but no casts. At the end of the primary anæsthesia (ether) during the operation, a severe glottic spasm resulted. This might have been due to accumulation of secretion. After operation, was very weak for a month, suffered much from angina pectoris, and died suddenly from latter disease. Specimen was shown. During life the left arytenoid cartilage and vocal band were so swollen that subjacent cord could not be seen. The right cord was forced into semi-abductor. There was no odynphagia. Autopsy also showed chronic nephritis, fatty heart muscle, and thickened pericardium.

Case II. *Small Round Celled Sarcoma of Larynx.*—Patient, male, aged fifty-three. Symptoms practically as in Case I. Pharynx was normal. The epiglottis was a fungoid mass. No laryngitis was observed. The right arytenoid was swollen and œdematous. There was swelling in the supra thyroid region, but none over the thyroid. High tracheotomy was done, as the patient refused radical operation. Died in one year from exhaustion. Both of these cases would have been favorable ones for partial laryngectomy.

Laryngectomy by a New Method.—Dr. Henry L. Swain, of New Haven, Ct, reported a case of laryngectomy performed on a German, aged forty two, who had an epithelioma which had followed on a simple fibroma of the right vocal cord, the latter having been known to have existed for a year previous.

The epithelioma waxed great and filled the entire larynx, so much so that tracheotomy was done under cocaine March 5th. March 18th the larynx was removed by Dr. W. H. Carmalt. Incision was made from the thyroid bone to sternum. A low tracheal opening was made, and a sponge Trendelenburg cannula introduced. Cross-incision made at top of wound to sterno-cleido mastoid muscles on either side. The larynx was then laid bare, and, bleeding being checked, a bistoury was inserted back of larynx between it and trachea. The trachea being liberated by a cut from a strong bistoury, the larynx was hooked up, and dissection begun from below upward. The anterior wall of œsophagus was carefully preserved until the arytenoid cartilages were reached. A cross cut was then begun, preserving a part of the mucous membrane of arytenoids and ary-epiglottic folds. The epiglottis was then cut across, its larynx freed, removed, and all bleeding checked. The epiglottis was then sewed on to the anterior wall of œsophagus, thus closing in the pharyngeal cavity and cutting off all communication from the wound in neck. Subsequently the wound in neck was sewed up tight, except enough of the lower part of median incision to allow of taking in the upper rings of the trachea, which latter were sewed into connection with skin flap, making a circular opening turned upward and forward. The wound was dressed with plain dry dressing. No tube left in trachea. Patient stood operation beautifully, although it lasted two or three hours.

The subsequent healing of wound followed without adventure, save a large stitch abscess above and back of trachea, which healed in a few days. Temperature got to 101° F. the second day, and then went down to normal or nearly so and remained. The internal wound at base of epiglottis was observed to heal by first intention and patient could swallow water from the first, could take fluid nourishment at the end of a week and regular hospital diet at end of second week. Internal and external wounds are both in healthy condition. Patient could make no audible sounds at first; later, hissing consonants were to be perceived, and now the briefest sentences and single words can be distinctly understood with the back turned, so that lip reading is eliminated. There is nothing more than a whisper to the voice, but it has gained so much of late in strength as to promise more.

Patient's condition at present prime, he working at his trade of a carpenter, wearing most of the time a tube in trachea.

Third Day, Friday, June 1st.

Exudative Pharyngitis.—Dr. W. C. Glasgow, of St. Louis, Mo., related the history of a child, aged ten months, large and robust, who took cold and had an otalgia without fever. Two days later, coryza came on and the temperature rose to 104° F., with morning remissions.

Its course was very irregular, like the fever of a septic process. Mucus poured from the nose in torrents, blistering the nostrils and also the skin wherever it touched the latter. It was so abundant that cloths had to be placed around the nose to take it up. The excoriations soon became covered with a whitish pellicle. There was also the same secretion from the fauces, where, on tonsils, uvula, soft palate, and pharynx, the exudate appeared. There was none in the nose. The patches were white, elevated, and left no raw surface on removal. They looked like blisters containing solid albumin. The exudation on the uvula was probably due to mechanical causes. There was prolonged aphonia and urgent dyspnœa with dysphagia. Fluids returned through the nose. The skin lesions were like those on the membranes, but the edges were raised. Adenopathies were wanting. The secretion was intensely alkaline. For treatment, sodium salicylate salve, and brandy were given internally, while locally peroxide of hydrogen was used. Aristol served well as a dressing for the skin lesions. A suppurative otitis occurred as a sequel. The whole duration of the case was three weeks. The secretion contained streptococci in large numbers, but no Loeffler bacilli. Dr. Glascow regarded the case as one of the protean forms of influenza.

Dr. Jonathan Wright, of Brooklyn, thought that, as streptococci were so very common, it was difficult to prove their causative relation in this present case. He had not found in the Eastern cities such exudative forms of influenza as had been reported from the West.

Dr. Glasgow replied that he had seen cases from Eastern cities. He had found benzoate of soda most helpful in all cases of solid œdema occurring in the course of influenza.

Singer's Nodes.—Dr. F. I. Knight, of Boston, spoke of the little nodule, as large as a millet seed, or larger, appearing on one or both vocal cords at about the junction of the middle and anterior third, after strain of the voice by prolonged use or wrong vocal methods.

This manifestation should be considered clinically as a separate entity, although pathologically, as far as examinations hitherto made have shown, the nodule is of the same nature as those occurring in the diffuse form, to which the term trachoma, sometimes applied to the single nodule, should be restricted.

Whether the term chorditis tuberosa, which has also unfortunately been applied to the diffuse form as well as the single nodule, should be retained for the latter is doubtful, as often there is no general chorditis; but if it is, its use should be restricted to the single nodule.

In regard to treatment, Dr. Knight said that in the cases he had met with up to this time, by rest, and astringents if there was also inflammation of the surrounding mucous membrane, the voice had been so far restored that he did not feel justified in risking cutting operations; but if, after this treatment, there should be in any case still no useful voice he should not hesitate to employ Dr. Rice's guillotine and remove the protruding portion of the growth if it could be engaged, hoping that the remainder would be more readily absorbed.

Dr. Knight said that he had been unable to learn the ultimate condition of the singing voice in any of the cases where an operation had been performed, and hoped that the discussion might furnish some facts in this regard.

Dr. J. W. Gleitsman had used the galvano-cautery in these conditions and had been well satisfied with the result. He also advocated chromic and trichloracetic acids.

Dr. S. W. Langmaid, of Boston, looked upon the condition as a circumscribed definite tumor. He had seen one case more posteriorly than those described by Dr. Knight. They generally occur in women and do well unless chorditis ensues The nodule is not vascular and is often the result of a previous chorditis. He had seen six or eight cases in all. He expressed some doubt as to the causative relation of a wrong vocal method, for these nodules are seen in singers who are able to satisfy the artistic demands of a critical public and consequently do sing well. The voice often improves sufficiently to serve for the dramatic stage, though its finer singing qualities may be permanently lost. Surgical procedures would not necessarily impair the voice unless much injury was done to the edge of the cord. Curetting might suffice.

Dr. Porcher asked if Dr. Knight thought that these nodes ever developed into papillomata; Dr. Knight responded in the negative.

Dr. Murray had seen four cases. One at Stoerck's clinic was treated with solid silver stick and steam inhalations with a perfect result. The node disappeared entirely. One case was in a boy seven years of age, also a singer.

Dr. Wright had presented the history of a case before the New York Academy of Medicine and asked if its members present believed that there was any relation between the condition and tuberculosis. If such existed it might be from dyscrasia or direct irritation from the lung lesion.

Dr. Swain had treated one case with silver nitrate. The cord looked fairly well except at one point, but the voice had not improved.

Dr. John N. Mackenzie had cured one case of the tuberous variety with lactic acid in concentrated solution.

Dr. T. R. French spoke of a case illustrating the value of long-continued treatment The woman had greatly overused her voice and several nodules were visible. One case looked as if the cord had been subjected to violence. He believed that surgical measures were contra-indicated. In the first case mentioned, local treatment had been continued three times a week for over two years and a half, weak astringents being used. The voice is now completely restored, though she tires more easily than before. The edges of the cords look perfectly straight but are a little thickened on one side. He did not believe in the association of the condition with tuberculosis.

Dr. W. K. Simpson, of New York, thought that the cause lay rather in the over-use of the voice than in a wrong vocal method. The nodules might come from laryngitis or from hemorrhage in the cords, the bleeding resulting from over-use and leading up to nodule formation. In one instance a linear hemorrhage on the under side of the cord came up into the middle line and was clearly seen where high notes were sounded by the patient.

Dr. Delavan did not believe in the association with tuberculosis. The existence of the two conditions is of course possible. Nodules sometimes appear in acute laryngitis, but the relation of these to the chronic variety is unknown.

Sarcoma of the Tonsil.—Dr. A. W. Watson, of Philadelphia, reported a case of a woman aged fifty-three who was well till last Christmas. Had a severe sore throat, probably a quinsy, discharging a little pus without relief. Severe pain continued, running to the ear. There was moderate swelling of the left tonsil and of the anterior faucial pillar, which was adherent. With this exception, there was no infiltration of surrounding structures. Considerable pain on swallowing was present.

One small gland was enlarged at the angle of the jaw, and engorged capillaries were seen at the surface of the tonsils. Medicine did no good. A deep incision was followed by free bleeding, but revealed no pus. A piece of the tonsil removed for examination showed the view characteristic of round-celled sarcoma.

Six weeks later, under cocaine, the tonsil, held out by vulsellum forceps, was, along with its adherent pillar, removed by successive short strokes with the galvano-cautery knife. Three weeks after, pain in the ear had nearly gone and the adenopathy had disappeared. There was no odynphagia. The peculiar features of the case were the sudden onset and the presence of so much pain and

dysphagia in view of the lack of infiltration of surrounding structures.

Importance of an Early Diagnosis of Malignant Tumors of the Throat.—Dr. J. W. Gleitsman, of New York, read a paper with this title. The author stated that he did not desire to ventilate the question of the possibility of an operation, in cases so far advanced that the decision had to be left to the patient as to whether he would prefer to slowly die after a tracheotomy, or to take the risk of a probable death by any attempt at removal.

At the present time there are three methods of procedure which have resulted in a certain number of cures. The endolaryngeal operation allows of temporary removal, but at times effects a lasting cure. If patients only come under observation early enough this method should be resorted to more frequently than it is. The first operation done in this way for epithelioma of the vocal cords was done by Schmitzler, in 1867, with no recurrence twenty years later. Reference was made by the writer to several other similar cases which are recorded in the recent literature of laryngology.

A possible relief is promised by the method elaborated by Coley, of treating these tumors by inoculations of erysipelas or of its toxic products obtained by the cold process.[1] One of Coley's patients had sarcoma of the tonsil which, under the erysipelas treatment, diminished considerably in size and had not increased after two years. Reference was also made to the use of methyl blue in cancerous tumors. In these latter, internal medication with this agent has given better results than its local application.

Regarding modern surgery the larynx and pharynx can be considered as analogous to the breast and uterus. But conversation with our leading surgeons elicits the fact that by far too large a number of cases are seen by competent men only when the patients have reached a stage when an operation is either impossible or extremely hazardous. Excepting trauma and sepsis, delay in operating is the most potent factor for bad results in surgery. Early diagnosis is indeed often difficult; but when once made, delay is both unjustifiable and unpardonable. It is better to avoid the use of the word "cancer" in our necessary conversation with our patients.

As to the operation itself, the case generally goes for this purpose into the hands of the general surgeon; and the laryngologist, therefore, cannot be accused, by his advocacy of operative measures, of selfish motives. Each case must be decided on its own merits—as to whether we shall do a tracheotomy only, or extirpate the larynx *in toto*, or do a modified laryngectomy after Cohen's method. Preniazek, a Russian surgeon, has had thirty-seven cases of laryngo fissure with the head hanging down, and has had only two deaths—one from diphtheria and the other from tuberculosis.

Of thirteen cases under Dr. Gleitsman's own observation the pharynx was involved in six, and the larynx in seven. Of the former four were cancer and two sarcoma (tonsil). Of the latter, six were cancer and one alveolar sarcoma. One case of pharyngeal cancer was operated upon three months ago and feels well now. The others died. Of the two tonsillar sarcomas one was inoperable, the other lived two years without recurrence after removal, but died by suicide. Of the seven laryngeal cases the six cancerous patients are dead and the sarcomatous case is living without known recurrence. Laryngo-fissure, with removal of the diseased tissue, was done twice; unilateral as well as total extirpation, each twice; tracheotomy alone, once. Death resulted twice from shock, twice from pneumonia (second and third). Only one had a recurrence after six months, and died from exhaustion. One with total laryngectomy did well for several months, but died of an intercurrent appendicitis.

In the discussion on the two preceding papers, Dr. Wright spoke of the difficulty in making an early diagnosis in such cases, even with the aid of the microscope, until the clinical features were well developed. He expressed a polite scepticism as to the accuracy of Coley's results. Some people seem to be immune against streptococcus infection. The paper was still further discussed by Drs. Swain, Simpson, Langmaid, and Casselberry.

Neurasthenic Throats.—Dr. W. Peyer Porcher, of Charleston, spoke of the intimate relations between the throat and the lungs, and how lesions in one place might excite symptoms in the other. Among the most common symptoms of neurasthenic throats were reflex cough, aphonia, and a spastic condition of the laryngeal muscles. Many of these cases seem to form the base of a subsequent phthisis. Illustrative cases are quoted to emphasize the main points of the paper.

Carbolic Acid in Cysts of the Larynx.—Dr. E. Fletcher Ingals, of Chicago, forwarded a paper on this subject. A case of cyst of the larynx occurred in a man, forty-three years of age, who had experienced some trouble with his throat for about two years, but had been annoyed by soreness for only a month, though there had been considerable cough for the previous seven months.

When he first presented himself there was hoarseness and continuous burning pain in the throat. One brother had died of consumption, but there was nothing in the patient's personal or hereditary history which seemed to account for his symptoms. His general health was good; weight normal; temperature and pulse, normal; he had a deep, loose cough, and expectorated about half an ounce of muco-pus daily, which subsequently appeared to be the result of a subacute laryngo-tracheitis and bronchitis. There were no abnormal physical signs over the chest, but an examination of the larynx revealed a large swelling of the left ventricular band and aryepiglottic fold, measuring about one and one-half by one centimetre, antero posterior and lateral diameters. The surface of this was uniform and smooth; the mucous membrane over it slightly congested, and the whole had the appearance of a solid tumor. After a preliminary treatment with resolvents, it was determined to inject the tumor with lactic acid. From ten to thirty minims of a thirty per cent. solution of this medicine were injected deep into the growth, three or four times, at intervals of two or three days. As the needle passed in, it had the feeling of passing through four or five millimetres of firm, soft tissue into a cavity. A laryngeal lancet was subsequently used, and a small amount of thick, semi-transparent, grayish fluid escaped, which caused some diminution in the size of the tumor; the contents, however, soon reaccumulated, and it was found that the injections of lactic acid had no influence upon the size of the growth. It was then determined to use deep injections of carbolic acid, which was employed in solutions in glycerine and water of from eight to ten per cent. of the acid, from fifteen to twenty minims being used at each injection, and the injections repeated once in from five to seven days. These injections were repeated eight times in all, twenty minims of the ten per cent. solution being used each of the last six times. At the end of this time the tumor had nearly disappeared, and the injections were discontinued with the belief that the cyst had been obliterated. The patient was subsequently seen at intervals of three or four weeks for three months after the last injection, and there had been no return of the growth. The patient felt that his throat was perfectly well, and it presented the appearance of a normal larynx.

The especial points of interest in the case consisted of the deeply seated position of the cyst, and the impossibility of removing it without removing a large part of one side of the larynx. Its walls were so thick that crushing, tearing, or cutting operations were out of the question.

Mycosis of the Pharynx and Tonsils.—Dr. Ingals reported twelve cases of mycosis of the pharynx and tonsil in order to place the histories on record. They offered nothing specially new, but illustrated the great

[1] See American Journal of Medical Sciences, May, 1893; also Post-Graduate, August, 1893.

superiority of cauterization with the galvano-cautery over other methods of treatment.

Four of the cases received practically no treatment. The other eight were treated by cauterizations with the galvano-cautery, and all were cured; in none has recurrence occurred so far as the author could determine.

An analysis showed that in fifty-eight per cent. the patient had for many years suffered more or less from sore throat, and in sixty six per cent. soreness of the throat had been present from four to eight weeks immediately preceding the discovery of the mycosis. Symptoms of dyspepsia were present in three cases, or twenty-five per cent., but in fifty per cent. of the cases it was distinctly stated that the patient was in general good health.

The plan followed in the treatment had been to burn off the growth and to pass an electrode, heated to a bright red heat, about one eighth of an inch into the tissue beneath it. Two or three patches were cauterized at each sitting, and the operation was repeated at intervals of about five days, according to the patient's convenience, two or three days being allowed to elapse between the disappearance of the soreness caused by one cauterization and the repetition of the operation.

The author believes that in some cases the disease had existed for many years before it was discovered; but in most of the patients he had seen it had apparently been of only a few weeks' duration. From his experience in two of the cases he believed that the disease might sometimes disappear under natural causes.

Etiology of Rheumatic Affections Due to Tonsillar Diseases.—Dr. H. L. Wagner, of San Francisco, forwarded a paper with this title: The tonsil has been justly termed by Gerhard a physiological wound—an inlet into the system guarded by leucocytes, which we have learned of late protect the body against the invasion of various micro organisms. If through inherited or acquired predisposition the energy of these leucocytes is diminished, or if the tonsil in a diseased state does not allow these corpuscles to migrate, then a soil may be given for infectious diseases, such as diphtheria, scarlatina, tonsillitis, follicularis, etc.

The sequences which sometimes follow these diseases are important to observe: paralysis of various parts of the body after diphtheria, and also articular rheumatic affections following follicular tonsillitis. The results gained by clinical studies and bacteriological investigations in follicular tonsillitis, followed by rheumatic affections, are what I particularly desire to refer to.

The question which presents itself is: Whether these rheumatic affections are produced by the germs (staphylococcus albus et aureus, Fraenkel's pneumococcus, etc.) migrating from the tonsillar tissues into other portions of the body, causing rheumatism—or whether they remain in or about the tonsils, sending forth and distributing their ptomaïnes or poisonous products into the system?

The result of my investigations, which I will give you in brief, show in follicular tonsillitis a migration of these germs, proving that rheumatism here is not caused directly by ptomaïnes.

Clinical observations show that the joints which are mostly in use are the ones generally affected; for instance, the ary-cartilages of the larynx of singers (5 cases), the knee-joints of shoe dealers—owing to the constant kneeling posture (2 cases), and the wrist joint of violinist (1 case), and bookkeepers (2 cases). Referring to the two cases above, where rheumatism of the knee-joint developed, the bacteriological investigation showed that the synovial fluid obtained by tapping of the joint contained the same micro-organisms as found in the diseased tonsil. I was also able to identify the same germs in the urine of nearly all the cases. The family and clinical history of all these patients showed no signs of rheumatism before the attack of this tonsillar disease.

Skulls of Cretins.—Dr. Harrison Allen, of Philadelphia, gave a demonstration on the skulls of cretins, showing the peculiar characteristics of this condition as influencing the size of the nasal chambers. The hard palate was shortened, the inferior meatus deepened, and in one instance the maxillary sinuses greatly enlarged. The skulls were from the Wistar Museum, at Philadelphia. He believed cretinism more common in America than is generally supposed.

Election of Officers.—At the executive session following the reading of papers, Dr. John O. Roe was elected president for the coming year. Rochester, N. Y., was selected as the place of meeting, the date to be determined by the council.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL SUNDAY—INCORPORATED MEDICAL PRACTITIONERS' ASSOCIATION—DEFENCE—PROTECTION—BUSINESS AFFAIRS OF THE PROFESSION—SIR B. W. RICHARDSON'S MISTAKE—COUNTER PRACTICE—THE ANTIS AND THEIR FADS—EXPERIMENTS IN HOSPITALS.

London, June 9, 1894.

Hospital Sunday is again upon us, and to morrow most of the places of worship in London will resound with appeals to the benevolent on behalf of the suffering. *The Lancet*, always a warm supporter of this movement, has this year repeated its plan of publishing a special supplement in aid of the work, and one hundred and twenty-five thousand copies of an abstract of this supplement have been distributed to the ministers of the various congregations. This supplement was first issued in 1886, and has been regularly continued since.

The Practitioners' Association has been duly registered as a company limited by guarantee under the Companies' Acts, 1862 to 1890. Its name is now the Incorporated Medical Practitioners' Association, and its objects apparently those of protection societies generally, to which is added the promotion of various reforms. In pursuit of these laudable objects, a special issue of the *Medical Times and Hospital Gazette*, a vigorous little two-penny paper which is the descendant of the *Students' Journal*, and the organ of the Association, has been largely circulated, containing full particulars of what has been and will be attempted. Hospital abuses, remuneration of medical men, the question of nurses and midwives, and some law proceedings have occupied much of the attention of this Association, and there is no disposition to burke any of the burning questions that other bodies seem to neglect. This Association seems really to have had its birth in the House of Lords Committee on Hospital Management, and several of its members gave evidence before that committee on the abuses of out-patient departments.

I do not know if the Council of this newly incorporated body expect to rival the British Medical Association, but they certainly promise to do work which has hitherto been neglected. While they consider that existing organizations successfully cover the field of scientific work and progress, they say they intend to be above all things practical and to carry out schemes of direct utility to the members. The business affairs of the profession, are therefore to be added to the great objects of protection and defence. Accordingly they propose to appoint solicitors to work for members at reduced charges (catch the lawyers so far imitating the doctors!); to act as agents in life and fire insurance, and for the transfer of practices and to collect debts. The profits of this kind of business—which some will think incongruous—are to be added to the reserve fund. Committees of arbitration are also to be formed, which may be useful in settling disputes and preventing scandal. A defence committee would perhaps prevent some of the prosecutions that have too often been unjustly brought against medical men, and an ethical committee might very well warn practitioners who are guilty of unprofessional conduct. You will see that very

much of this programme is the neglected work of the British Medical Association, and might all be done by it. While it, however, ignores its duties and opportunities, it may be desirable to establish another organization. The British itself began in a small way, and it is impossible to predict how rapidly the young rival may grow.

One thing strikes me as a mistake: the little society with its little organ should have pitched its subscription at a figure in accordance with its size and actual position. It cannot all at once compete with a huge co operative journal society which has sacrificed so much professional honor for the sake of a great advertising connection.

Sir Benjamin Ward Richardson has "put his foot in it" with the general practitioners. He has actually proposed in his *Asclepiad* (occasionally pronounced as if sleepy-head) to legalize counter-prescribing by druggists. If there is one abuse more injurious to the profession and dangerous to the public than all others, surely it is this wide-spread encroachment of men in a province for which they are unfitted. Bad as it is to endure the competition of unauthorized and unqualified quacks of every kind, what would the consequence be of legalizing the practice of the great shop-keeping quack? Convert every dispenser into an authorized prescriber, and the "doctor's shop" would no longer be a phrase to laugh at. Ignorance would prescribe for all minor ailments a pennyworth of a drug or a shilling nostrum according to the willingness of the patient to disburse. This is certainly a solution of the problem of cheap dispensaries and out-patient abuse which no reformer has contemplated. I hope Sir Benjamin will have the courage to say he repents the rash proposal, which was no doubt dropped in a thoughtless moment—an error often committed by those who suffer from attacks of *cacœthes scribendi*. This is by no means the first blunder of Sir Benjamin's on medico-political matters, but he could hardly be betrayed into one more serious.

Mr. A. Arnold, whose chief distinction is perhaps his name, has been speaking in Piccadilly on vivisection, and said if such cruelty to animals were permissible because good results were obtained we might sanction the vivisection of malefactors and children. No doubt he knows the fallacy of his own foolish utterance, but anything is good enough for an audience if it will give a little notoriety.

Another cry—apparently got up by the crazy antis—is against experiments on patients in hospitals. It is rather too bad of these faddists to attack our hospitals on the eve of the Sunday collection. But we need not wonder, for so many falsehoods have been circulated by the anti this or the anti-that egotists, and vouched for by persons who ought to know better, that the most monstrous statements excite no surprise, although their repetition by some cheap newspapers is bringing disgrace on the editorial function.

OÖPHORECTOMY vs. ŌŌPHORECTOMY.

To the Editor of the Medical Record.

Sir: I have noticed of late, especially among gynecologists, a mispronunciation which violates all the rules of etymology, and is excessively offensive to the ear to anyone who remembers the origin of the word. The word I refer to is "oöphorectomy" which of course, as your readers well know, is derived from the Greek word ᾠόν, an egg, a word of two syllables and not of one. It would be just as excusable to pronounce "zoölogy" "zōōlogy," or "oölite," "ōōlite," as to unite the two o's in the pronunciation of oöphorectomy. The dictionaries, as your readers will find, all put the diæresis over the second "o," and I trust that our gynecological friends will be willing to introduce it into their pronunciation, and not offend the ear and the taste and violate the proprieties by such mispronunciation.

Very truly yours,

W. W. Keen.

Philadelphia, June 28, 1894.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 7, 1894.

	Cases.	Deaths.
Tuberculosis	58	102
Typhoid fever	9	2
Scarlet fever	52	11
Cerebro-spinal meningitis	0	2
Measles	61	8
Diphtheria	201	47
Small-pox	11	4
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Orloff-Davidoff Prize.—A prize of 10,000 rubles ($5,000) is offered by Count Orloff-Davidoff for the discovery of a certain cure or preventive of cattle plague. The efficacy of the remedy is to be proved by the same standard as those known to science as protective against small-pox, anthrax, etc. The award of the prize is in the hands of the Curator of the Imperial Institute of Experimental Medicine of St. Petersburg, acting on the advice of a committee of experts selected for the purpose. The competition is open to the whole world with the exception of active members of the above-named institute. The description of the proposed remedy must be clear and complete; it must be sent in, under the ordinary conditions as to concealment of the identity on the part of the author, on or before January 1, 1897. The award of the prize will be made on January 1, 1899. If no remedy satisfies the committee, a further competition will take place, and the award made on January 1, 1902. This may stimulate the search for the desired remedy, but it may also lead to the suppression of any such discovery, if made, until the award of the committee is announced.

Legislators Going to School.—The German Cultus Minister has, in response to repeated stimulation by a sanitarian deputy, consented to organize systematic courses of instruction in matters appertaining to public health for the special benefit of members of the German Legislature. Lectures are to be given by the professors of hygiene of the various German universities on the principles of hygiene. Probably, in the fear lest the legislators might not go to the lectures, it has been arranged that the lectures are to come to them, for they will be given within the precincts of the Legislative Chamber itself. The idea thus put forth is delightful, and it ought to be Americanized at once. If we could only have in Washington lectures on economics for the populists, lectures on statesmanship, money, and taxation for Republicans and Democrats, lectures on verbigeration and morals for all, it would greatly promote the usefulness of our law makers, and give an enormous impulse to the activity of our educators.

Cold Baths in Whooping cough.—Dr. Maurice Springer reports, in *L'Union Médicale* of June 2, 1894, a case of pertussis in a child aged one month, in which the sole treatment consisted in the giving of cold baths to which powdered mustard was added. The child recovered.

Living Anatomical Charts.—The British War Office is considering the advisability of instructing all soldiers in Her Majesty's service in the principles of first aid to the injured. Some genius has offered the startling and original suggestion that every soldier should have the leading arteries mapped out on his body by dotted lines tattooed in India ink, so that any of his companions may be able to arrest dangerous hemorrhage should he chance to be wounded.

FEEDING AFTER WEANING.[1]

BY WM. L. STOWELL, M.D.,

NEW YORK.

FEEDING an infant after it leaves its mother's breast involves the whole subject of dietetics. We have just had a course of three lectures (Professor Chittenden, Cartwright lectures) on one part of digestion, yet are now to compress the entire matter into a ten-minute review. The review must be cursory in the extreme.

The infant at birth is a carnivorous mammal, composed of nitrogenous and fatty matters, carbohydrates, and salts of lime, potash, etc. To maintain the little creature, all these substances must be supplied. The mother's milk is an emulsion of fat containing these ingredients. It is, therefore, the perfect food. The infant has a simple digestive tract which secretes very little digestive fluid of any kind. The simple milk is absorbed with little difficulty and little waste.

With the passing months, changes take place, anatomical and physiological. At six or eight months teeth appear and the salivary glands become active. This suggests the ability to eat a little of the food of adults, *e.g.*, starches. From the eighth to the twelfth month the teeth come more rapidly, the child becomes very active, uses up tissue, and needs more material to build with. Now is the time to wean and supply additional food. The exact time cannot be set. A mother who is not strong, has become pregnant, or feels nursing a tax on her constitution; should begin weaning at six or eight months. Should the child not thrive, wean early. If both mother and child are well, the physiological changes are such that the baby can leave the breast partly at ten months, and completely before a year. The transition should be gradual except in case of acute illness of the mother. Begin by giving cows' milk once or twice a day, and nursing only two or three times.

Human milk contains: proteids, 1.78 per cent.; fats, 3.83; sugar, 6.84; salts, 0.23, a total of 12.68 solids. (Leeds's average twelve mothers.) Cows' milk contains: proteids, 3.76; fats, 3.75; sugar, 4.42; salts, 0.68, making total solids 12 61. (Leeds's ordinary bottled milk.) Human milk then differs from that of the cow in containing more fat, 2.25 per cent. more sugar, less salts, and but half the proteids.

Because of the excess of proteids, cows' milk needs to be diluted one third or one half with water, depending upon the digestive power of the infant. The slight acidity of cows' milk may be disregarded in infants of six months or over. Lime-water or soda may be added earlier. Ordinary dairy milk contains from ten to twelve per cent. of cream. When such milk is diluted one half, the fats are too low; extra cream must be added. Jersey milk contains eighteen to twenty per cent. of cream, and hence requires only the addition of water, and a little sugar, possibly. I have raised Jerseys, and raised babies on Jersey milk, and heartily approve of it. It is not logical to declare Jersey milk too rich, and forthwith give directions for adding cream to ordinary milk until it is of Jersey standard. One dealer served me with milk containing eighteen per cent. of cream, another, equally well known, supplied milk only seven per cent. cream. Obviously the two could not be treated alike. Ass's milk is very nearly the same as woman's milk in composition. "Strippings" is also better than ordinary milk, being richer in fat. Neither is practicable, so they need no discussion.

In warm weather all milk should be heated to 168° F., *i.e.*, Pasteurized, to destroy ferments and prevent souring. This temperature kills tubercle bacilli, typhoid, or other germs that may be lurking in the fluid. The process of sterilizing renders casein less readily coagulated, destroys milk-sugar, and causes proteid matter to adhere to fat globules, retarding their digestion. These changes are of no importance clinically, except in weak children.

Perfect nutrition demands waste and removal of tissue, as well as new aliment, *i.e.*, complete oxidation. Sugar and starch take up much oxygen, and if given in too great quantity will detract from what should go to the albuminoids. It is the excess of one ingredient that so often begins the malassimilation that ends as rickets. The starches easiest to prepare and digest are potato, oatmeal, and barley. The two last are added to milk as diluents and for their mechanical effect on casein, even in infants only a few months old. They have no food value, however, until six months, when ptyalin is present in sufficient quantity to act on them. Oatmeal prevents constipation by causing increase of peristalsis, whereas barley tends to check diarrhœa. Choose between them accordingly.

Condensed milk is a popular substitute for breast milk. The weight of medical authority is heavily against it. As ordinarily diluted it contains less than half the albuminoids and fat needed, or if diluted to their proper proportion the sugars are doubled. As a natural result we have two kinds of babies brought up on it—one plump, but without any staying powers in case of illness, the other a starving little skeleton. Condensed milk is only to be commended when travelling, or as a temporary change when other food disagrees.

Lactose forms one half the solids of milk. Its oxidation maintains the body heat. If it be deficient, the little infant wastes and starves. As the infant of ten months grows stronger and more hungry give him stale bread or crusts to bite on. Zweibach, and toasted bread (moistened), or crackers will also supply starch, partly converted into dextrin and so easy of digestion. In baked potatoes the starch granules are finely divided, so they should be preferred to boiled potatoes. By the twelfth month soft boiled eggs may be given. In the egg we have fourteen per cent. of nitrogenous, and 10.5 per cent. of fatty matter. An egg diluted with water and sweetened makes a good substitute for, or addition to, milk. Soft boiled it digests in three hours. Additional nitrogenous food may be had in broths of beef, mutton, or chicken. Beef-tea to be of any value should be a cold infusion of a pound of steak to a pint of water, not heated until just before serving. Prolonged cooking coagulates the albumin of meat and only extracts the salts It is poor food. Meats contain much potash and lime, for which reason Routh says children need much meat to build up their bone and muscle.

During the beginning of the second year the anterior molars appear, an indication that the child is ready to masticate food. He may now have rare roast-beef to chew and suck the juice from, not to swallow. Beef is one of our best nitrogenous foods, containing 20 per

[1] Read before the Section on Pediatrics, New York Academy of Medicine, May 10, 1894.

cent. nitrogen; next comes mutton, with 18 per cent.; poultry, with 21 per cent., and nearly 4 per cent. of fat. Fish is 18.1 per cent. nitrogen, and 2.9 per cent. fat; mutton is a little easier than beef to digest but not so rich. Graham bread, rice, and corn bread can be added to the dietary now that there are teeth enough to break them up thoroughly. Bulky food stimulates digestion by causing increased muscular action of stomach and flow of juices. Concentrated foods are to be avoided as not promoting natural activity. However, liquid foods will often check vomiting without medicine.

A thin sandwich of stale bread with scraped beef and a glass of milk is a good breakfast for a babe of two to three years of age. A dish of plain meat-soup with baked potatoes, a boiled vegetable, and bread will be his dinner at noon. By three o'clock he will want crackers and milk. At six o'clock a cup of custard, or bread and butter with milk, should be the last meal of the day.

Physiologists say that children absorb three or four times as much carbon per pound weight as adults. This accounts for their eating so out of proportion to their weight compared with their parents.

At two years of age, or thereabout, the child has his twenty deciduous teeth. He can eat all plain food of a proper table, and thinks he should have everything he sees. He should not be allowed even tastes of unsuitable articles, only such food as is to form his diet. All fried food is difficult to digest. Re cooked meats are improper. All so-called rich food is interdicted, as the system is not strong enough to wrestle with foreign substances or excess of natural diet.

During the second year fruit is admissible. Scraped sweet apples are enjoyed, and digested in one hour and a half. Baked apples in milk with crackers make a good supper. Juice of oranges is good in the morning. Bananas, if very ripe are rich in sugar and much liked by the little ones. When green or unripe, bananas are largely starch. If eaten too green and too rapidly by too young a child it is pernicious food, otherwise good.

In arranging a dietary regard must be had for season, cold or hot climate, sluggish or active temperament of the child, etc. The exact weight or exact age of the child is not a proper criterion. Two atoms of hydrogen unite with one of oxygen to form a molecule of water; but you cannot be sure that a given number of grains of nitrogen will produce a definite number of foot pounds of force, or that so much sugar will produce so many heat-units.

It is often forgotten that the child needs a large amount of water, even if his diet be chiefly fluid. I have therefore included water in the table below, which I have compiled as a summary of dietetics in the young.

The following dietary may serve as a basis for directions to parents and nurses:

FREQUENCY AND SUBSTANCE OF MEALS.

8 Months, 5 Meals.

7 A.M. (*a*) Milk.
(*b*) Milk and rusk.
10.30 " (*a*) Oatmeal or barley in milk; sugar or malt.
(*b*) Beef-tea.
2 P.M. (*a*) Egg in milk, sweetened.
(*b*) Stale bread and milk.
5.30 " (*a*) Milk and cracker or zwieback.
(*b*) Milk and oatmeal or barley.
10 " (*a*) Milk.[1] Total milk, 1½ pint.

1 Year to 1½ Year.

7.30 A.M. (*a*) Rusk or cracker and milk. Banana.
(*b*) Soft boiled egg; milk. Orange.
11 " (*a*) Milk; bread and butter.
(*b*) Baked potato; milk.
2 P.M. (*a*) Beef-tea; light pudding.
(*b*) Bread, butter, bread in meat gravy from a roast.
(*c*) Meat, roast, to suck on.
5.30 " (*a*) Bread and milk. Prune juice.
(*b*) Cocoa; custard.
10 " (*a*) Milk, if awake. Total milk, 2 pints.

Two later periods in childhood deserve a moment's consideration.

Table of Food Values.

Food.	Nitrogen. Tissue-forming Proteids.	Carbon.	Fats.	Carbohydrates. Heat-giving. Sugar.	Carbohydrates. Heat-giving. Starch.	Salts.	Water.	Total solids.	How prepared.	Hours for digestion.
Human milk (Leeds)	1.78	3.83		6.84		0.23	87.32	12.68		2.00
Cows' milk (Leeds)	3.76	3.75		4.42		0.68	87.39	12.61		2.00
Eggs (Pavy)	14.00	10.50				1.50	74.00		Raw	1.50
									Soft b'l'd	3.00
									Hard b'l'd	3.15
Bread (Letheby)	8.10	1.60			51 00	2.30	37.00		Stale	2.00
									Hot	3.15
Potatoes (Letheby)	2.10	0.20		3.20	18.80	0.70	75.00		Baked	2.30
									Boiled	3.30
Beef cooked (Ranke), lean	19.30	3.60				5.10	72.00			
" " " fat	14.80	29.80				4.40	51.00			3.00
Turkey (Letheby)										2.30
Fowl "	21.00	3.80				1.20	74.00			4.00
White fish (Letheby)	18 10	2.90				1.00	78.00			2.00
Apples (Freseninus)	0.22	Pectine, 2.72		7.85		0.44	85.04	Insoluble, 2.96		
Bananas, ripe (Corenwinder)	4.82	Fat, 0.63		19.65	Traces.	0.79	73.90	Cellulose, 0.20		

Water, Croton (Chandler) (grains per gallon) sodium chl., 0.40; sulphates of potash, soda, and lime, 0.617; carbonates of lime and magnesia, 2.74; silica, 0.62; organic matter, 0.67. Total solids, 5.03.

Stimulants.—The testimony of physicians is almost unanimous against alcohol for children in health. The small percentage of sugar or oxidizable material in wines and beer is more than offset by the injuries to digestion and the nervous system. All the wisest men use stimulants guardedly, even in infantile disease. Tea and coffee have a very considerable value in checking tissue waste, and indirectly supplying nitrogenous matter and salts; but these virtues are entirely counterbalanced by the ill-effects of tannin and thein; the one causing colic, etc., the other making the child nervous, fretful, and peevish. Still the children of the poor consume great quantities of both. The millionaire's pet and the laborer's youngster start with the same anatomy, but are rarely reared on the same diet.

At the sixth or seventh year, when the deciduous teeth fall, the child must be urged to chew his food thoroughly. If he begins to attend school that will form an excuse for bolting meals.

Still later, at puberty, unusually rich or highly spiced food should be avoided lest it increase sexual excitement in the immature.

Bring up the child from the beginning to eat slowly and at regular times as much as he wants. The rules of time and quantity will be on a sliding scale in different families. In feeding infants, as in the whole practice of medicine, we must fix the principles, and prescribe with common-sense according to the case in hand.

28 WEST THIRTY-SIXTH STREET.

[1] All milk Pasteurized, if Jersey, or in warm weather.

TYPES AND METHODS OF RESPIRATION.

By J. GARDNER SMITH, M.D.,

NEW YORK.

PHYSICAL DIRECTOR HARLEM BRANCH Y. M. C. A.; SPECIAL INSTRUCTOR IN PHYSICAL TRAINING PUBLIC SCHOOLS; MEMBER COUNTY MEDICAL SOCIETY; VICE-PRESIDENT HARLEM MEDICAL ASSOCIATION; MEMBER A. A. A. P. E., ET .

We are told by the best authority (Genesis ii. 17) that when the Lord breathed into his nostrils man became a living soul. Ever since that time respiration and life have been closely related. In all forms of animal life air seems a necessary factor. In man we know that through the lungs air enters the blood. Passing through the nostrils, the pharynx, the larynx, the trachea, the larger bronchial tubes, the smaller bronchial tubes, the more minute air-passages, and finally the delicate air-cells, the oxygen of the air by a process of osmosis passes through the microscopic wall of these cells into the blood; and carbonic-acid gas passes from the blood in the reverse direction till it is exhaled again through the nostrils. Each breath then carries oxygen to and eliminates carbon dioxide from the blood.

This interchange depends upon the demand by the body; the extent of breathing surface within the lung; the elasticity and action of the thorax (or chest); upon the nervous mechanism controlling each, and, not least, upon the purity of the air we breathe. Bodily demands, of course, depend upon mental or physical exertion. The man who never makes much physical or mental effort may live to a good old age, but he is never prepared for an emergency, such as injury or disease of a portion of the lung, nor can he enjoy any violent effort with safety; and in his later years his general health, if it has not done so already, will deteriorate.

The extent of breathing surface within the lung varies with the individual. His heredity, his early years, acute or chronic disease of the bronchial tubes or lung substance determine this condition to a certain extent. He may, however, materially improve and increase this function by judicious respiratory exercises (so-called "pulmonary gymnastics"). This practice should be begun early, the earlier the better, and be continued throughout life.

The capacity of the thorax, too, may be increased by judicious exercise in breathing. The passive individual in a healthy condition at each inspiration inhales perhaps thirty cubic inches (Kirke) of air. This is called "tidal" air. The average individual without special practice in breathing or vigorous physical exercise of some kind can inhale a variable quantity over and above this, called "complemental" air. Again, this individual can exhale, by forced expiration, a variable quantity over and above the ordinary tidal air called "supplemental" or "reserve." There still remains in the chest after a forced expiration a certain quantity of "residual" air, estimated (Kirke) at one hundred cubic inches. This quantity also varies with the ability of the individual to contract all the diameters of the chest. In my statistics of 2,000 men of average age, about twenty-three years, the total capacity of the chest ("complemental," "tidal," and "supplemental" air) was about two hundred and fifteen cubic inches, and this quantity is about the same for 2,000 men since that reckoning. This capacity by practice was increased by fifteen cubic inches (average) within one year.

The interchange of air within the lungs and the chest capacity depends largely upon an intelligent understanding of the mechanics of respiration and persistent practice of the methods of respiration. Proper co-ordination of the muscles of the thorax is highly important. Many men of ordinary intelligence, and many more with "thin gray matter," have no control of the chest. Some do not even know how to inhale, to say nothing of the practice of the various types of respiration.

There are three main types of respiration in man—superior thoracic, diaphragmatic or "abdominal," and inferior thoracic—illustrated by the following photographs.

[1] Read before the Harlem Medical Association, March 7, 1894.

Mechanically, the thorax is a conical box bounded laterally by the ribs; the sternum and costal cartilages anteriorly; the ribs and spinal column posteriorly; the diaphragm, a dome-shaped muscle with a tendinous centre forming the base. This conical box is capable of movement in every direction. Muscles raise the ribs upward and forward, increasing the antero-posterior diameter; muscles rotate the ribs outward and upward and raise them laterally like the bail of a pail, increasing the lateral diameter; the diaphragm moves downward, increasing the vertical diameter.

The size of the chest thus increased the air within the lungs becomes rarefied; the pressure within the thorax becomes less, and immediately the external air, with its continual pressure of fifteen pounds to the square inch, rushes in to fill this "tendency to a vacuum." Of course it is highly important that the nostrils and other air-passages and the chest and abdominal wall be free from constriction or obstruction.

Upper chest or superior thoracic breathing (see Fig. 1,

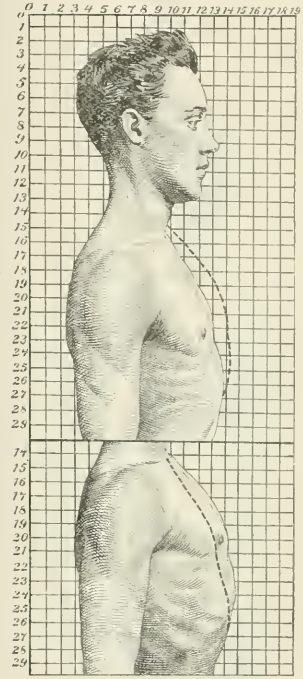

Fig. 1.

a to *b*) may be practised on command "inhale" and "exhale," or "one," "two," and "three," "four." On the first command, or first two counts, raise the upper chest, upper and forward, to the fullest extent (see *a* to *b*). Do not raise the shoulders. On command "exhale," or "three," "four," the chest should recede (see *b* to *a*); keep head erect. Pupils will grasp the idea more quickly and better by placing the left hand on the upper chest, inhaling and exhaling through the nostrils. This may be done to music (count of sixteen). The photographs show the proper movement of the chest.

Abdominal or diaphragmatic breathing (see Fig. 2, *a* to *b*). On command "inhale" and "exhale," or "one," "two," and "three," "four," lower and raise the diaphragm. This action presses the abdominal organs downward, and thus, on the first command of "one," "two," the abdomen protrudes (see *a* to *b*). Do not move the chest wall or bend the body.

To aid in understanding this exercise, press upper chest with left hand and place right palm just below lower end of the sternum. At every inhalation the right hand should be pushed forward, and on second command, or "three," "four," the abdomen should recede underneath the hand.

Practise to count of sixteen or more or to music. Always breathe through the nostrils.

Lower side chest or inferior lateral thoracic breathing (see Figs. 3 and 4, *a* to *b*). On command "inhale" and "exhale," or "one," "two," and "three," "four," distend and contract the lower chest laterally. On the first command, or "one," "two," the ribs are rotated outward and raised laterally (see *a* to *b*), as one would raise the bail of a pail. Thus the broadest part of the chest is enlarged and much air is inhaled. The writer examined one man with this part of the chest extraordinarily developed, who had a chest capacity of over four hundred cubic inches. (The spirometer recorded no higher.) On count "three," "four," or "exhale," expel the air by contracting the lower chest. In this exercise the upper chest and diaphragm should remain passive. The backs of the fingers or point of index fingers pressing lightly at about the ninth rib will enable one to understand this rather difficult exercise. The best singers have almost com-

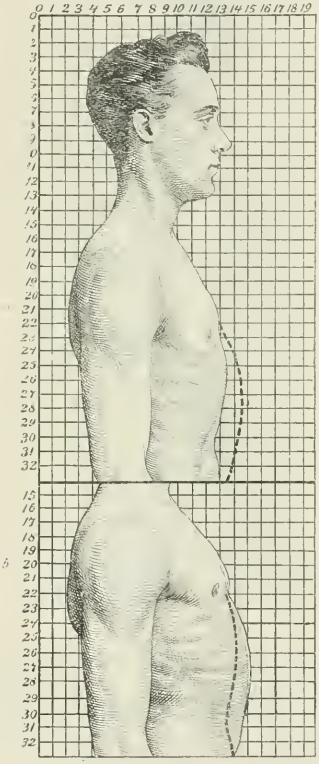

Fig. 2.

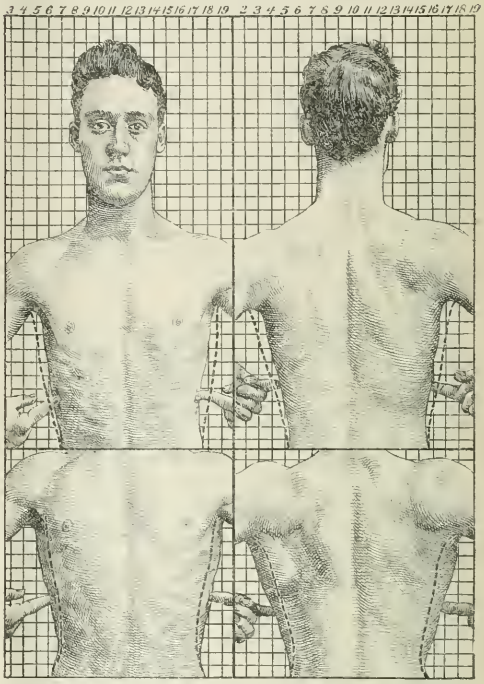
plete control of lower chest and diaphragm and breathe but little with upper chest.

Obstacles.—Of course it is highly important in diaphragmatic and inferior thoracic breathing that there be no constriction about the waist or lower chest. Many ladies cannot run or exercise vigorously mainly because of such constriction. Again, some children find difficulty in breathing with the mouth closed. In most of these cases there is some deformity or disease within the nostril, which should receive surgical attention. Another very important consideration is pure air. The air of a well-ventilated room, class-room, or gymnasium may be beneficial, but every opportunity for practice in the out-of-door air should be improved. Running or other vigorous exercise stimulates respiration, because the blood demands more oxygen. The individual who understands how to use his chest is able to meet this demand more readily. In the individual with a large chest capacity, who understands how to breathe, who is free from disease of bronchial tubes or lung-tissue and without heart disease, shortness of breath is seldom seen. Breathing exercises are most beneficial



Figs. 3 and 4.

when practised after muscular exertion. They should occupy an important place in physical training.

The effects are better development and control of the thoracic muscles; more power in speaking and singing; a healthier condition of the lungs; improved circulation of the blood within the lungs; more rapid and efficient aëration of the blood; better general health.

307 Lenox Avenue.

New Drugs and New Names.—Our esteemed English brethren must be especially keen on new drugs, and in particular on new names of a proprietary character. A casual glance through the advertising columns of *The Lancet* (which is sometimes considered a conservative journal) gives one quite a new idea of modern materia medica. The following list of "new drugs" is taken from a single issue: "nepenthe, malakine, virol, pepsalia, pumitine, cactina, celerina, antinervine, cerebrine, papain, anestile, opiatine, lintus tussi, kreochyle, vapo-cresoline, chiralta liq. cocoatina, izal, bynol, bovril liquor sedans." These are not all, but they are sufficient to show the pharmaceutist's fancy, and the appreciation of it by the British mind. To the student, and even the recent graduate of medicine, all these things must appear quite unintelligible, and he must feel that having learned the materia medica of his text-books, he must begin again and learn that of the manufacturer.

A FEW APHORISMS RELATING TO OBSTETRICS.[1]

By A. C. EWING, M.D.,

SALT LAKE CITY, UTAH.

What to do, and what not to do, in the management of labor—that is the question.

No branch of a physician's practice requires more self-poise; and where so many complications arise commanding our sympathy and demanding our skill, as that of obstetrics, and when disease and death follow a normal case of labor, the cause can be traced to none other than to ignorance or mismanagement.

With these preliminary remarks, I shall advance a few aphorisms relating to obstetrics.

1. Examine the urine a week or so before the expected confinement. Albumin need not cause alarm, unless present in large quantity, in which case the woman should be restricted to milk diet, given one-tenth grain sulphate spartein four times a day, and bowels kept open with cream of tartar; the object being of course to relieve congestion of the renal veins.

2. Make no digital examination without first cleansing the hands and nails, together with the external genitals, with a solution bichloride mercury, 1 to 2,000 and ethereal soap.

3. Empty the rectum thoroughly with an injection of warm water.

4. Make as few examinations as possible during progress of labor, and each time dip the hand first in the antiseptic solution.

5. If presenting part emerges slowly from the womb, do not allow your impatience to so get the better of your judgment as to induce you to "assist nature" by pulling upon the os. I am strongly of the opinion that about all the deep pathological tears, calling for surgical interference, found on the right and upper anterior sides of the cervix, are caused by the finger of the accoucheur.

6 If "pains" are sluggish, change the position of the patient.

7. Do not rupture the "bag of waters" too soon, as it, when intact, favors, I believe, the posterior rotation of the face.

8. Should a posterior rotation of the occiput occur, and nature fail after a reasonable length of time to effect a delivery, apply the forceps and turn the occiput to the front, by rotating either to the right or left, as the position of the babe would indicate.[2] This manœuvre of the forceps can be executed without danger if care be exercised, turning the head not more than a quarter of a circle at a time, then pausing a moment for the shoulders to follow. After this is accomplished the instruments should be removed and re-applied.

9. In making traction on the child's head with the forceps, unlock them about every thirty seconds, else the engorgement produced by continued pressure of the instruments might cause a hæmatoma of the brain or dura.

10. To prevent a rupture of the perinæum.

When the occiput is emerging from the vulva, remove the right hand from the forceps and with it support the soft parts, while with the left you continue slight traction upward until the bridge of the nose reaches the anterior border of the perinæum, when the instruments are quickly removed; now, in order to avoid a rupture, especially if an expulsive effort is being made, hold the head *in statu quo* until a relaxation takes place; then, with the thumb and first two fingers of the right hand, push the perinæum down and under the chin, allowing it to rest on the palmar surface of the fingers. The next pain will expel the head, which is grasped by both hands and pulled upward—delivering the under shoulder first.

11. Should a rupture occur, repair the injury at once, using the large iron dyed silk.

12. Do not become impatient if the placenta does not follow quickly, but wait, say a half or even an hour, before an attempted forcible delivery is made. Should, however, a violent hemorrhage occur, empty the uterus at once, by disinfecting the hand, introducing it into the womb, detaching the placenta, and allowing it and the hand to be forced out together.

13. The source of uterine hemorrhage following labor arises almost always from the open and now no longer useful utero-placental vessels. Nature, ninety-nine times out of a hundred, prevents hemorrhage arising from this source by filling up these tortuous vessels and plastering over their open mouths with coagulated blood. Therefore:

14. Do not use Crede's method, and for two reasons: first, that the act of squeezing out the placenta dislodges at the same time from the anfractuosities and vessels this plastic coagulum, inviting streamlets of blood to follow the non-pressure of the hand, causing in all probability a hemorrhage instead of preventing it. The second reason is, that a hemorrhage following after this method of forcible expulsion, necessitating, as it usually does, a constant hand-pressure over the uterus for half an hour or more, while it may not prevent absolutely the reformation of nature's cement, would, in my opinion, cause paralysis of the contractile fibres of the womb, rendering them incapable of responding to the stimulus of ergot or to anything else. (When I see a woman who is suffering from uterine subinvolution, I unhesitatingly lay it to the undue paralyzing pressure it has received.)

15. For these passive hemorrhages where, so soon as the hand is removed the hemorrhage goes on, I rely on one teaspoonful of laudanum rather than two or three of ergot.

16. After the birth of the child, gently knead the abdomen with the finger tips of the left hand, using barely force enough to feel the uterus beneath. This gentle friction excites uterine contraction far better than rough massage, expelling the placenta almost as quickly, and is rarely, if ever, followed by unpleasant hemorrhages or after pains. This slight finger-pressure should be continued a short time after the placenta is expelled.

17. In early abortions, before atrophy of the blood-vessels of the mucosa takes place, the hemorrhage comes greatly from this engorged mucous membrane instead of entirely from the placental surface, as in full term. To stop it, do not use ergot or compression, but approximate the inner surfaces by removing the decidua with the placental forceps and dull curette. This is to be followed by a hot antiseptic (preferably carbolic acid) intra-uterine douche.

18. Have the vulva kept well covered with sublimated cotton to catch the lochia and prevent hetero-infection; and, in addition, if a clean and competent nurse is in attendance, order given, night and morning, for five days, warm antiseptic vaginal douches.

19. Wash the babe's eyes the moment it is born; and, in dressing the navel, use borated cotton saturated with glycerine.

20. Restrict the diet the first three days only, after which have the bowels moved either by an enema or the compound licorice powder. (If there is much flatus, use instead a full dose of castor oil and turpentine.)

21. Keep the woman in bed two weeks if possible, and the first four days give a capsule containing 1/2 gr. ergotine and 2½ grs. quinine morning, noon, and night. This tends, I believe, to prevent fever and hastens the process of involution.

22. If surgery is your specialty, and you are called to a case of confinement, use extra precautions in cleansing the hands and nails; in fact, it would be wise, if your practice in surgery is extensive, to let obstetrics alone, for I care not how skilful you may be (and surgeons as a rule are skilful), you will, sooner or later, lose from septic infection the wife of some one, and it may be, alas! the wife of your dearest friend.

[1] Read before the Salt Lake Medical Society, April, 1894.

[2] E.g., when in a right O. P. Iliac position, turn the forceps to the right, and when in the left O. P. I. position, turn to the left. The child can be turned, however, and without danger, even when in a direct O. P. position.

THE DYNAMICS OR POWER OF THE INTERNI.[1]

By FRANCIS VALK, M.D.,

PROFESSOR OF THE DISEASES OF THE EYE, NEW YORK POST GRADUATE SCHOOL AND HOSPITAL.

In the static condition of the external muscular apparatus of the eyes, we find these organs directed forward, slightly downward, about fifteen degrees below the horizon, and slightly convergent, so that the visual lines are directed toward a point about twelve feet distant in front of the eyes. In this position the visual lines will form an angle, whose base extends from each centre of rotation in the eyes and whose apex lies at the point mentioned above. This angle is called the muscular mesoropter; and when the eyes are fixed in this position, the external muscular apparatus is supposed to be completely at rest, with binocular vision.

Starting from this position of rest, the eyes are, by the active force of the straight muscles of the eyes, moved consensually, in different directions, according to the sensations produced on the retina by the rays of light. It is this active power of the muscles, particularly that of the interni and its antagonist, the externi, which I offer as the object of this paper.

In the examination of the eyes and the muscular apparatus, by which we may endeavor to draw certain conclusions or arrive at any specific results, we are accustomed to compare the examination of one hundred cases. I have therefore selected this number, from the last cases on my note-books, in the hope that this examination may be of some service in the correction of asthenopic troubles. For the past year or more I have been interested in the active power or dynamics of the interni, and so have tested that power as well as that of its antagonistic muscle in this series of cases, and I have been somewhat surprised at the result. All these cases have been examined in my office with, I think, reasonable care, and I feel satisfied the results are very nearly accurate, and will leave the final results to speak for themselves, as I am not prepared to say just on what lines all these cases may be treated.

When we study the refraction of the eye, with all its complex apparatus, each part of which works so beautifully in conjunction with the other, and the complications that may arise, we are apt first to consult Donders and note his remarks. So as I turn to him I find that even before his work was published, or some forty years ago, many bold surgeons, at that time, were performing tenotomy of the externi for the relief of asthenopia, not only in myopic cases, but in all others. In many cases they must have been successful, but in others, with the usual enthusiasm of the profession, it was carried too far, and the results were far from successful, even disastrous in some cases. Still, it was continued, more or less, until Donders found that most of the cases of asthenopia were due to a shortening of the optic axis, or hypermetropia, and the tenotomy of the externi passed into "innocuous desuetude." Then for many years we followed the teachings of Donders, and gave convex glasses to all our asthenopic cases, until the present day, when we have two questions presented to us. Firstly, that of insufficiency of the straight muscles, either in their actions vertically or horizontally, as advocated by Dr. George T. Stevens. And secondly, since we have used that excellent instrument of precision, Javal's ophthalmometer, we find astigmatism, due to the curvature of the anterior surfaces of the cornea, unless neutralized by the curvature of the posterior surface (Tschering) or that of the crystalline lens. This is the active cause of all asthenopia, and must be corrected.

I propose, at present, to take a conservative view of both propositions, and believe we will find cases where relief will depend on either condition. Correcting the last proposition of astigmatism first, and then, in case of failure, turning to the first proposition, where I believe we may find success for the relief of the asthenopia.

In looking over the literature of this subject in our text-books, I failed to find any positive statement in reference to the dynamic power of the straight muscles. In Saelberg Wells's last edition, I find the active power of the interni as about twenty to thirty degrees, and that of the externi as six to eight degrees. In Noyes's work on "Diseases of the Eye," I find the best exposition of this subject; but in his table of one hundred cases his results seem very different from my own examinations. He reports seventy-five per cent. with insufficiency of the externi, with nearly fifty per cent. emmetropic, while I have only two per cent. emmetropic. I cannot consider a low degree of hypermetropia as an emmetropic eye. Dr. Stevens considers that the active power of the muscles should be respectively about fifty degrees for the interni and ten degrees for the externi, or in the proportion of five to one; but in my examinations I have never found them as high as Dr. Stevens, except where the muscular power has been exercised by prisms, when this result may be obtained.

From my own examinations, I am inclined to think that if the power of the interni stand to that of the externi in the proportion of four to one, or even three to one, we will have no muscular asthenopia; in other words, the interni should be three or four times stronger than the externi, for comfortable work at the reading distance. This will give sufficient reserve power according to Landult, for all useful purposes.

In my examinations, I regret to say, I have been disappointed in the tests for the dynamic power of the muscles of adduction and abduction; as with Von Graefe's vertical diplopia test, Stevens's phorometer, and Maddox's rod test, I have found some cases exactly opposite to that of the prism test. Hence, I have confined my tests to the simple power of each individual muscle to overcome the deviation of a ray of light from a candle placed at fifteen feet, passing through a prism with the apex placed over the muscle to be tested, using the test without a colored glass placed over the other eye. This method may have its faults, but I think we should have the eyes in the best possible conditions to develop the full muscular power, that is, the power to fuse the images by causing them to fall upon the macula in each eye.

I do not think we maintain that condition when we reduce the retinal impressions by a disk of colored glass or by a vertical displacement of the images, so that the rays may fall upon a less sensitive part of the retina, and in both instances we lessen the stimulation for a correct fusing of the images.

As an instance of my preference for this simple test, I find that, in forty-eight cases, the vertical diplopia test agreed with the prism test in only twenty-nine, and was exactly opposite in the remaining nineteen; in other words, the first test would show esophoria or homonymous images, indicating weakness of the externi, while with the prism test we would find that the dynamic power of the externi exceeded that of the interni, according to the proper proportion. Either one or the other must be wrong, and I think we may depend on that which allows the eyes to be tested under the same conditions as exist when the eyes are used at their daily work.

In compiling the result of one hundred cases of asthenopia I have used the following tests. Refraction, phorometer, vertical diplopia, prism test. Also recording the treatment, as the correction of refractive errors if present, the prism ordered, operations, if any, performed, with the final result as far as possible.

As regards the refractive errors, I have used atropine in some doubtful cases, otherwise not, as I agree with Roosa that at the present time it is not necessary to put our cases to the inconvenience of blurred vision, from paresis of the accommodation, but I have verified my trial by glasses, with the retinoscope, the ophthalmoscope, and the ophthalmometer of Javal. I believe, when these four

[1] Paper read before the Ophthalmological Section of the Academy of Medicine, New York City, November 19, 1893.

tests agree, we cannot be very far from the exact condition of refraction in our cases. I place the examination with retinoscopy first, as I have found that the most reliable and correct objective test in reference to the final results of the vast majority of cases. It gives the refractive condition of the dioptric apparatus, showing any astigmatism and the axis very rapidly and correctly. I use the plain mirror only at a distance of forty inches and read my results, as shown by the retinal reflex, without reference to any so called shadows, or by using a lens of one dioptry placed before the eye. I may differ with some of my colleagues in this respect, but I am satisfied my examinations are correct, as they have been confirmed by the examination under atropine. In many cases I have noted the existence of an astigmatism of one-fourth of a dioptry by this simple test.

The ophthalmoscopic test I consider a very valuable and useful one, but I have not been able to confirm an astigmatism of less than one half dioptry, while in the use of the ophthalmometer of Javal I have fully published my result, but I now depend more upon the approximation of the mires and the size of the image, reading off the radius and the degree of the astigmatism in dioptries, on the arc, than I do upon the overlapping of the image of the mires. I find these markings much more correct, while in most cases it is not necessary to allow the usual one-half dioptry. It is also difficult at times to tell the exact overlapping, but we can readily see when the edges of the mires touch in the primary and secondary positions. My rule is, in all refraction cases, that these objective examinations shall agree, and I expect to find the same result in the trial by glasses.

In all these cases as tabled, the refraction was corrected by glasses first, and a fair trial given; and I believe, in a large majority, they were relieved of their asthenopia, even though the active power of the interni was found far below that of the normal standard; but if they were not relieved, then I felt that I must seek some other cause for their asthenopia, and endeavored to correct whatever muscular insufficiency I could find, relying in all cases on the simple prism test.

The refractive conditions of this series of cases also seem to present some features of peculiar interest, as they do not agree with any tables I have noted. Taking the cases in their sequence of frequency I find:

	Cases.
1. Simple hyperopic astigmatism, axis 90°	40
2. Compound hyperopic astigmatism, axis 90	26
3. Compound myopic astigmatism, axis 180°	8
4. Hypermetropia	5
5. Simple myopic astigmatism, axis 180°	4
6. Mixed astigmatism	4
7. One eye—Am. the other Ah	4
8. Simple hyperopic astigmatism, axis 180°	2
9. Emmetropia	2
10. One eye, Ah., the other Amh	1
11. One eye, Ah., axis 90°, the other Ah. 180°	1
12. One eye, H. w. Ah., axis 90°, the other same, axis 180	1
13. Compound myopic astigmatism	1
14. One eye, Ah., axis 90°, the other M. w. Am., axis 90	1
Total	100

In most tables of refraction we are accustomed to note hypermetropia as the prevailing condition;[1] but now, with the improved methods of examination and perhaps increased proficiency, I find that the largest number have simple hyperopic astigmatism, and the next largest the same condition, associated with hypermetropia, these two classes forming more than sixty per cent. of the entire number, and evidently the prime factor in the causation of asthenopia.

Passing now to the test which forms the object of this paper, I noticed, in many of my cases, examined in the past year, that the tests before mentioned for insufficiency did not give satisfactory results, so that I have been compelled to rely entirely upon the simple prism test. This shows the power of the straight muscles of the eye to turn it on the centre of rotation, so that the visual line shall be coincident with the rays of light passing through a prism.

You are, no doubt, all familiar with the simple test of placing the apex or angle of the prism over the position of the muscle to be tested, and increasing the size of the angle until the muscle loses its power to form a single image, and diplopia results.

Taking this as our test and then as our standard power, that the muscular power of the interni shall be to that of the externi as at least three to one or, better, four to one—Noyes says six to one, I found in this series only sixteen cases with that result. In the largest number, I found the power of the muscles equal, or as one to one, the total number being thirty-seven of this series. The rest of the cases varied in the proportionate power of the two muscles, in some the power of adduction was too great as compared with abduction, and in others exactly the reverse condition, and the power of abduction exceeded that of adduction. To place my results in tabular form I found.

Taking the power of the externi as one, then we have: one to one, 37; to one and a half, 5; to two, 20; to three, 12; to four, 4; to five, 4; to twelve, 1; to fifteen, 1; and to fifty, 1. In all of these the interni exceeded the externi, except the first thirty-seven cases. Now taking the power of the interni as one, and we have: one to one and a half, 3, and one to three, 1, while in three cases there was a very decided difference in each eye. Of the entire number only sixteen were within the standard limits; showing that in a vast majority of my asthenopic cases there was an insufficiency of the interni. "Noyes on Diseases of the Eye," p. 195, says: "In this proving, great diversities will appear according to the condition of refraction, especially will weakness of adduction appear, with myopia. On the other hand, defective abduction will more frequently be found in emmetropia and hyperopia and astigmatism."

I was surprised at the above result, as I expected it would be similar to Noyes's examinations; yet they seem to be just the opposite. We have only forty-nine in which the power of adduction exceeded that of abduction; but in only one half of these cases did it reach anywhere near this normal standard, as I have suggested; and when it was near this normal, then I find that in all my cases they were relieved by glasses.

In four cases I found the power of the one eye different from that of the other, both the interni and the externi being different in their proportions to each other; also in three cases there existed a constant diplopia, two showing esophoria, or weakness of the externi, of 5° and 30° respectively; with one case of exophoria, or weakness of the interni of 15°.

My treatment of this series of cases has been as follows: In all, the refraction was first corrected by glasses. When this did not prove satisfactory, I then examined the power of the muscles, and in eighteen cases, or nearly twenty per cent., ordered prisms combined with the correcting glasses. In four cases the interni was exercised by prisms three times a week, with relief for various periods. In two, partial tenotomy was advised and refused. In the three cases with constant diplopia, I did a complete tenotomy; and in six cases I did a partial tenotomy, with relief and decided improvement in the power of the muscles to overcome the prism test; so that in one-fourth I thought it advisable to correct the insufficiency as I found it, before I could get relief from their asthenopic symptoms

My indications for the extent of my tenotomies has been as follows: If I find there is a constant diplopia, with a deviation of the visual lines of ten to fifteen degrees or more, I find the muscle I decide to cut, with as slight a laceration of the conjunctiva and capsule of Tenon as possible; then with a very small hook beneath, I cut the tendon completely free from the eyeball, and allow the wound to heal without sutures. I believe the results of such an operation, when the vision is normal in each eye, will be about ten to fifteen degrees. If I de-

[1] See my paper before the State Medical Society, on Our Refraction Cases.

cide to perform a partial tenotomy, then I find my indications in the preponderance of power in one muscle over its antagonist, as compared with what I consider the normal balance as before stated.

So if I find the proportion as one to one, and the case is not relieved by glasses after a fair trial and thorough examination, I proceed to operate. This operation I perform by finding the muscle with a very small strabismus hook; then with a very small pair of scissors I cut the fibres of the tendon above and below, always leaving one small fibre in the centre of the tendon intact. I have found the results of that operation about three to five degrees as shown by the prism test.

We now come to the conclusions that these series of cases seem to present:

1. That in more than fifty per cent. of our asthenopic cases we will find that the power of the externi exceeds that of the interni, in comparison with the usual proportions that should exist between these muscles; in other words, that insufficiency of the interni is much more frequent than is stated in the text-books. I found only three cases of insufficiency of the externi.

2. That I place very slight reliance on any test for insufficiency of the muscular power, when we reduce the visual impressions of one eye by any means. Consequently, I can only rely upon the old test of the actual power of each individual muscle to turn the visual axis of the eyeball, coincident with a ray of light, deviated by a prism, from a candle placed at twenty feet from the person examined. In forty eight cases the vertical diplopia test did not agree, and was exactly opposite to that of the prism test in nineteen cases.

3. That in cases where the proportions of the muscles are as one to one, we may exercise the weak muscles for a reasonable time or as long as their power will increase, but I would state that I have found this exercise useful only in weakness of the interni. Or we may order prisms, combined with the glasses, with the base over the weak muscles. They may afford relief, and I have not found any of my cases develop a latent insufficiency from their use. In some cases these means afford, for a time, complete relief; but there may be a return of the muscular weakness; in other words, the improved power obtained by exercise or prisms is not constant.

4. That in all cases the error of refraction, either simple or with astigmatism, should be corrected by suitable glasses, and these should be worn for a month at least, before we attempt to correct any muscular insufficiency.

5. That, in diplopia, we should do a complete tenotomy, carefully performed, with as slight a laceration of the tissues as possible.

Lastly, that, in insufficiency well marked, after the results of several trials with the prisms are the same, we may then perform a partial tenotomy, as stated, with full confidence of a good result.

Measles in Samoa.—Dr. Davies, of Savaii, Samoa, writes to the *British Medical Journal* an account of the first invasion of measles into that island group. The disease was brought there in September, 1893, and in the following three months about 1,000 of the entire population of 34,500 died from its effects. The epidemic was mild and few died during the period of fever and eruption, the great mortality being due to the sequelæ and complications. The deaths were principally from gastritis, enteritis, diarrhœa, and dysentery. A few died from suppressed measles. The craving the natives manifest for raw fish, unripe or over-ripe fruit, and especially half cooked fresh pork, became morbid during the period of convalescence. Many, lest they should be told to avoid these, abstained from procuring foreign medicine. Nine-tenths of the deaths could have been prevented by care in diet, and even the worst cases of diarrhœa and dysentery yielded readily to treatment. Those patients who placed themselves under intelligent medical supervision, and who followed out the directions as to medicine and diet nearly all recovered.

Clinical Department.

HYDRONAPHTHOL IN PHTHISIS PULMONALIS.

By CARL B. SMITH, M.D.,
BINGHAMTON, N. Y.

Since January 1, 1893, I have been using hydronaphthol hypodermically in the treatment of phthisis pulmonalis with the following results: Out of 31 cases, in all stages, that I have treated I have had only 9 deaths, 8 are enjoying fair health to day but are incurable and 14 have been cured completely. I use it in the strength of grs. v. to ʒ j, and the following are the effects: The hectic fever disappears, the appetite returns, the cought lessens, the lungs clear, and the patient commences to gain in weight, some having gained as much as four pounds in one week.

In one case which I tested with the microscope (Ehrlich staining) the bacilli were found to disappear from the expectoration.

In all my cases I did not give either creosote or cod-liver oil, and can only give the credit of my success to the judicious use of hydronaphthol.

At the present time, after having practised this treatment for more than a year, I look for a cure, in the incipient stage, inside of three weeks; in the second stage, fifty per cent. cured inside of five weeks; in the last stage, life prolonged and some cures, but I will have to work further in this stage.

Working from the germ theory I used hydronaphthol in three cases of lobar pneumonia, and in each case the temperature dropped from 102° and 103° F. to normal; after the first treatment the cough loosened, and after the third treatment they were cured.

REPORT OF A CASE OF FRACTURE OF THE PELVIS, FRACTURE OF THE FEMUR, AND LACERATION OF THE BLADDER; RECOVERY.

By W. B. CUNNANE, M.D.,
SANTA BARBARA, CAL.

Fracture of the pelvis is said to be uncommon in men, rare in women, and almost unknown in children. It is usually produced by a crushing force, such as a caving of earth or stones in a mine, catching the body between two objects moving in opposite directions, or the passage of a heavy wheel across the pelvis.

There is usually a great deal of obscurity attending the diagnosis; and, even when the fact of the fracture is clearly made out, it may be very difficult, or almost impossible, to locate the exact line of separation. Examination by rectum, and in females by the vagina, may enable one to arrive at greater certainty, but frequently the most careful exploration may fail to determine the extent of the injury.

The gravity of these fractures usually depends upon the number and extent of the complications present, rather than the injury inflicted on the bone.

This fracture, especially when it takes place in children, occurs so infrequently that I deem the following case sufficiently interesting to the profession to make a report of it.

G. M—— was a native of California, female, aged five years, copper color, black hair and eyes; well developed but small for her age. She had measles when three years of age; and one year ago was confined to bed four weeks, on account of an injury to the head, produced by a fall; recovery complete.

Her present injury was caused on April 5th, by the wheel of a truck, heavily loaded with hay, passing diagonally across the anterior surface of the body, from the middle of the right thigh to the lower margin of the ribs on the left side.

On inspection: Dorsal decubitus; the left eye ecchymosed and the surrounding skin abraded; the left hand presents a contused appearance, and there is lateral bending of the second finger. There is a contused mark, about two inches wide, passing diagonally upward from right to left, across the pelvis, just to the left of the symphysis pubis. The left lower extremity is lying on its outer side flat upon the bed, and drawn up toward the trunk. The right lower extremity presents a shortened appearance, with some deformity about the middle of the thigh; the foot rotated outward and lying with its external margin flat on the bed.

On superficial examination I made a diagnosis of contusion of left eye; fracture of second phalanx of second finger of left hand; oblique fracture of right femur at junction of upper with middle third; fracture of the left os innominatum, or a separation of its primary centres, and probable injury to some of the pelvic viscera. The fractures are all simple.

The pain incident to making a careful examination and applying treatment was so intense that it was necessary to administer an anæsthetic. Therefore I requested assistance, and at the suggestion of the family Dr. R. J. Hall was called. Having to wait about two hours for his arrival, during the interval I gave morphia sulphate for the relief of pain.

As soon as the doctor arrived the little patient was placed under the influence of an anæsthetic, and with the finger in the rectum a careful examination was made; but we were unable to secure distinct crepitus, neither could we make out the exact line of fracture of the os innominatum The fractured femur was placed in a plaster-of-Paris bandage without extension, the plaster enveloping the hips and trunk to the axillæ. She was then returned to bed and instructions given the parents to maintain perfect quiet, to preserve the urine for future inspection, and administer light nourishment.

April 6th.—Pulse, 120; temperature, 101° F.; respirations, 28. She maintains the position originally assumed; the kidneys acted three times during the night, and the urine contained a quantity of blood. She did not sleep much during the night, and is crying with pain in the left inguinal region. There is extensive swelling in and around the hip joint extending downward almost to the knee. The inner side of thigh, high up, and the left labia are very much ecchymosed, swollen, hard, and painful to the touch; the swelling and ecchymosis extending from the symphysis pubis, anteriorly, to the anus, posteriorly, not passing beyond the median line, nor above Poupart's ligament. The eye, hand, and right lower extremity are doing very nicely, no swelling or pain.

We cut the plaster bandage where it encircled the hips about two inches up its middle, anteriorly, for the purpose of relieving pressure on the ilium. Not finding sufficient injury of the external genitals to account for the discharge of blood in the urine, we came to the conclusion that it was produced by laceration of the bladder, or internal portion of the urethra. Having arrived at the above inference we desisted from further examination, agreeing to await developments, and should the symptoms indicate the necessity of it, perform laparotomy.

April 7th.—Pulse, 100; temperature, normal; respirations, 25. The kidneys acted frequently during the past twenty-four hours, but the urine did not contain any blood. She is resting quietly now, and slept moderately well during the night. She maintains her original position; the swelling of left hip and thigh increasing, ecchymosis more marked, and cries with pain if disturbed. The eye, hand, and right lower extremity progressing nicely toward recovery.

From April 7th, to the date of discharge, May 5th, convalescence was progressive and uninterrupted, except by a mild attack of rubella, which produced a slight rise of temperature, sick stomach, and looseness of the bowels, lasting about twenty-four hours.

The dorsal decubitus; the entire extremity lying on its outer side flat upon the bed, the thigh flexed to its extreme limit upon the trunk, and the leg on the thigh, which position was maintained during the first three weeks patient was confined to the bed; the extensive exudation and effusion existing in and around the hip joint extending downward almost to the knee; the deeply situated ecchymosis and exudation into the left labia, its adjacent and subjacent tissues, not passing beyond the median line; the pain incident to the pressure of the plaster of Paris on the ilium disappeared immediately after it was divided up the middle, anteriorly; the intense pain which was produced whenever an attempt was made to move the limb or pelvis, and the discharge of blood in the urine, all combine to form an aggregation of symptoms which point to the correctness of the diagnosis. To be sure, we were unable to trace, with the finger in the rectum, the line of separation, but all of the other symptoms, subjective and objective, indicate fracture of the os innominatum, or separation of its primary centres, and laceration of the bladder or internal urethra.

At the present writing, June 2d, she walks with a perceptible limp in the right leg, which is due to about two ctm. shortening; there is, also, a sort of a shuffling movement similar to that of a woman after an unusually hard confinement; otherwise recovery is complete.

A NEW CARDIAC TONIC DOSIMETRIC GRANULE.

INDICATED IN CASES WHERE THE HEART'S ACTION IS IRREGULAR, WEAK, OR DIMINISHED IN TONE AND IN NUTRITION.

BY EDWARD C. MANN, M.D.,

MEDICAL SUPERINTENDENT SUNNYSIDE SANATORIUM, NEW YORK; MEMBER MEDICAL SOCIETY OF THE COUNTY OF NEW YORK; MEMBER BROOKLYN PATHOLOGICAL SOCIETY; HONORARY MEMBER MEDICAL SECTION IMPERIAL UNIVERSITY OF KHARKOFF, RUSSIA; PRESIDENT OF NEW YORK ACADEMY OF ANTHROPOLOGY, ETC.

In the treatment of nervous and mental diseases, and especially of inebriety and the morphia habit, we find mechanical difficulties and nutritive disturbances associated with valvular and neurotic affections of the heart. We cannot use digitalis in these cases without the great danger of getting up a condition of defective nutrition and secondary degeneration of the heart. We have in these cases to properly tone and increase the nutritive condition and working capacity of an enfeebled or irregular heart. We want a remedy that will at the same time nourish the heart muscle and slow a rapid and quicken a slow heart. We want a remedy the physiological action of which will be to establish a regular rhythmical action of the heart. This we can obtain very satisfactorily by the cardiac tonic dosimetric granule which we present to the profession. We are in a position to day to get a much higher degree of certainty in the administration of medicinal agents by the use of alkaloids, glucosides, resinoids, or organic acids, as medicinal agents, instead of the often complex and variable crude drugs which characterized old methods of treatment. These "active principles" are in many cases transmutation products, that is, they are obtained from the native substance by the action of a series of chemical reagents, and sometimes by the additional action of heat. Some of the alkaloids do not exist in the plant, apomorphia, for instance, which cannot be extracted as such from the opium, but is made by the action of heat and hydrochloric acid, from morphia. In this new method of dosimetry, and particularly by hypodermatic dosimetry, we can, by our knowledge of the exact chemical identity of our remedy, and of the precise quantity injected into the system, determine the nature and degree of the effects of this definite substance upon the physiological processes, both in health and disease, with a degree of accuracy hitherto unknown in the science of medicine. We know, furthermore, that an exact amount of the active principle reaches the lymph spaces and circulatory channels, when from its chemical

nature we can give it hypodermatically. Never before in the treatment of disease have we been able to treat it so exactly and obtain such certain and permanent relief as we can to-day, by dosimetry, and particularly by hypodermatic dosimetry. What we need now is better adaptable chemical forms of the "active principles," alkaloids, glucosides, or other definite active principles, and then we shall be in a position to have a new, exact, and scientific system of therapeutics. Hand in hand with this must go an exact system of feeding our patients (proteid diet) which shall require the least vital force and oxygen to digest, assimilate, and appropriate the food ingested, and give the most force and energy.

The formula for the cardiac tonic dosimetric granule which I use is as follows. Each dosimetric granule contains:

R. Morphia ..... gr. $\frac{1}{32}$
Strychnia ..... gr. $\frac{1}{134}$
Atropine ..... gr. $\frac{1}{3\,6\,0}$
Caffeine ..... gr. $\frac{1}{6\,7}$

We have here a granule with a fixed therapeutic activity which can be used hypodermatically, if desired, by simply dissolving it in water, and which, clinical observation proves most satisfactorily, will impart to the heart a better nutritive vitality, increased working-power, and a regular rhythmical action. It is well to bring the patient down to a restricted diet of milk, buttermilk, eggs, or raw oysters, and to correct all gastric or hepatic disturbances, to relieve the alimentary organs of their engorged condition, states which I always have to direct my attention to in the affections of the heart in cases of alcoholism, and very often in cases of the morphia habit. The use of this dosimetric granule we have always found followed by a rapid improvement in the strength and rhythm of the heart's action; and we recommend confining the use of digitalis to those cases where we need a powerful cardiac stimulant, in cases of threatened collapse, when one or two of the cardiac tonic dosimetric granules may be dissolved, and a hypodermatic tablet of $\frac{1}{1\,0\,0}$ gr. of digitaline added to it, as the most appropriate heart stimulant. Nitro-glycerine and sulphate of sparteine would also be indicated in such extreme cases, $\frac{1}{1\,0\,0}$ to $\frac{1}{5\,0}$ of the former by the mouth, with $\frac{1}{4}$ to $\frac{1}{2}$ gr. of the latter hypodermatically. I keep a solution of the sulphate of sparteine made up of the strength of 16 grs. ad aquæ ℥j., and standing by this a bottle of nitro-glycerine tablets $\frac{1}{5\,0}$ gr., and always use them simultaneously in emergency cases. In the treatment of the morphine habit also I have for years been accustomed to rely upon this latter combination for two or three days after complete withdrawal of the morphine to obviate and antagonize the psycho somatic suffering of the patient.

ANOMALOUS FŒTAL NUTRITION IN TWIN GESTATION.

By JOHN C. HUPP, M.D.,
WHEELING, W. VA.

On the second day of May, 1894, I encountered a phenomenon not heretofore observed in an obstetrical experience of forty-seven years. The mother of four children, in the seventh month, she alleges, of her fifth pregnancy, gave birth to very decidedly decomposed twins, one fœtus being very many times smaller and more completely decomposed than its twin sister. There was only one placenta, which was attached to the ordinary-sized cord of the larger fœtus, which was not larger than a thread, encircling its neck three times, and after tracing one end to the umbilicus I traced the other end to its attachment to about the middle of the cord of the larger fœtus, and around this attachment there were three or four cherry-like projections. The smaller fœtus, with or without a placenta, notwithstanding its anomalous connection, could not have been nourished through a cord so diminutive, and this, to me never-before-heard-of union, doubtless caused the death of the larger fœtus. My impression is that the insufficient nutrition of the smaller fœtus caused its death, and the resulting pyogenic material was conveyed to the larger one with fatal result.

REPORT OF THE USE OF CRUDE TUBERCULIN ON COWS.

By IRWIN H. HANCE, M.D.,
SARANAC LAKE, N. Y.

Being desirous of having the cows in the Adirondack Cottage Sanitarium free from any tubercular taint, a test was made on the herd with crude tuberculin. The herd consisted of eight cows such as are found on the ordinary country farm; to all outward appearances they were free from any disease. The day preceding the first test inoculations their morning and evening temperatures were taken per vaginam for comparison and were as follows:

May 21st.	A.M.	P.M.
1	100.5	102.6
2	101.0	.....
3	101.0	101.0
4	100.8	100.8
5	101.5	101.4
6	101.4	101.8
7	101.2	101.4
8	100.5	101.8

In looking over the literature at our command Dr. Hewetson, of Montreal, was unable to find any detailed account of dosage and temperatures; it was therefore deemed advisable to use a small dose to begin with; double the amount was given six days later to make the test reliable. The solution used contained 0.1 of Koch's lymph in each c.c. The inoculations were all made in the loose folds of the neck, just in front of the foreshoulder. Needles with very strong shanks are needed because of the thick hide.

May 22d, 8 A.M.—0.050 was inoculated in each cow. The temperatures in degrees Fahrenheit were:

May 22d.	8 A.M.	2 P.M.	8 P.M.
1	100.6	101.8	102.4
2	101.0	101.5	100.8
3	101.4	100.8	100.8
4	101.4	100.8	100.2
5	101.4	101.2	100.6
6	101.0	101.6	101.0
7	101.6	101.2	100.6
8	101.4	101.6	100.8

A comparison of the temperatures for the two days shows a negative result.

May 28th, 7 A.M.—One decigramme was administered to each cow. During the day the temperatures were as follows:

May 28th.	7 A.M.	2 P.M.	8 P.M.
1	100.6	101.8	100.8
2	101.0	101.4	101.2
3	101.4	101.0	100.8
4	101.4	100.8	100.6
5	101.8	101.2	101.0
6	101.6	101.2	101.0
7	102.2	101.6	101.4
8	101.2	101.6	101.0

On this occasion the results were equally satisfactory.

A single glance over all these temperatures shows that the normal temperature of a cow per vaginam is about 101° F. The only exception was cow number one, which was an old matron; her afternoon rise of temperature cannot be considered reactionary since the evening temperature of the day on which she received one decigramme of lymph was only one-fifth higher than that of the morning.

The ease and simplicity of the administration, with the thoroughly practical and efficient results of this test, places in the hands of everybody a simple means of discovering this very prevalent disease.

Two Deaths under Anæsthesia occurred recently in two successive days in Birmingham.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 21, 1894.

SYPHILIS OF THE EPIDIDYMIS.

IN affections of the testicle, as they are usually spoken of, the diagnosis is ever a matter of great interest, and, indeed, often of much importance, and it is not enough for the physician to pronounce the case one of "swollen testicle" and order rest and hot poultices. Many of the diseases which attack the various structures contained within the scrotal envelope have been carefully studied, their salient features pointed out to aid in arriving at just conclusions regarding them, and their etiological bearings definitely traced. There are others which, it would seem, have not received the attentive study their more or less frequent occurrence demands. According to Dr. C. W. Allen, this is true of the syphilitic changes which take place in the epididymis while the testis proper remains unimplicated. In a paper just published in the *American Journal of the Medical Sciences*, he writes his views upon what we must acknowledge is a relatively little discussed question. The first writings of importance concerning the early syphilitic epididymitis are attributed to Engelstedt (1861), and to Drow two years later. "Since then," the writer says, "little has been added to the literature bearing upon it if we except the brief writings of Szadek."

We would here like to call attention to a Paris thesis published by Cuilleret, in 1891, entitled "Étude sur l'Épididymite syphilitique secondaire," which has evidently been overlooked. Since it touches upon some points which have been omitted in Dr. Allen's paper, we will review its chief features and conclusions. The writer believes that epididymitis by itself is a frequent manifestation of the secondary period, especially at its beginning, but that it passes unperceived, for the double reason that it occasions no discomfort and has a marked tendency to spontaneous regression. Habitual examination of the organs alone can determine its relative frequency, for its chronic course is benign and has no tendency to permanent alteration or destruction of the tissues. The opinion is, however, expressed that its presence indicates a rather pronounced attack of syphilis, which should be carefully treated, and that the probabilities favor serious manifestations in the after-stages. The matter of differential diagnosis does not appear to present many difficulties. Gonorrhœal epididymitis is certainly much more frequent, but its acute and painful symptoms would exclude this affection, though it would seem that, as an exception, a case may be acute. The induration is located in the head of the organ and is extremely hard. Diagnosis from beginning tuberculosis must offer greater difficulties where all other signs of syphilis are absent, and the element time, and possibly test treatment, it seems to us, would have to enter into the problem's solution. The first mentioned paper takes up a rather different phase of the question, and the proposition is advanced that syphilis attacks the epididymis at almost any stage as well as in the early secondary period, in the absence of any other evidence of the disease, and when there have been no symptoms, perhaps, for many years. This view is supported by a number of clinical observations, several of which add decided weight to the arguments, while some of the others are not so convincing. One difficulty which stands in the way of accepting the results of treatment as strong proof of the syphilitic nature of a pathological condition, is that mercury and the iodides are so often beneficial where there is not the least suspicion of a specific taint. This may be true even of tuberculous processes, as the writer admits in commenting upon the last of his series of cases, and says coincident evidence of tuberculosis in other organs must be looked for.

A point in differential diagnosis between this and the chronic enlargement so often left after gonorrhœal epididymitis, is that in the latter the tail of the organ is the part involved, while syphilis implicates mostly the head. There is no doubt that castration is still now and then performed for supposed tuberculosis or malignant growth, where syphilis is the real cause of the abnormality.

For this reason alone such clinical studies of the question are not amiss, for while they aid in saving an occasional testicle by means of the iodides, they tend to bring about a better understanding of the whole subject of enlargement of the epididymis; and so far as syphilis is concerned, it must be confessed the field has not been overworked.

THE RISE OF APIUM GRAVEOLENS.

IT is with considerable interest that we have watched the rise into therapeutical prominence of that toothsome adjunct to the dietary, celery. Without any adventitious aids from the physiological laboratory or critical clinical studies, it has become a formidable rival to the mystic sarsaparilla and ginseng as a popular remedy. It does not pretend to purify the blood, to be sure, but it calms the nerves, a task of even greater magnitude in these *fin de siècle* days. Apium graveolens, or celery, is, we believe, a close cousin to apium petroselinum, or parsley, but somehow it is petroselinum alone that has won serious medical attention. This latter plant is aperient and diuretic, and helpful in amenorrhœa, dysmenorrhœa, and allied female complaints. Some years ago Dr. Ransom asserted that celery also had some influence on the urinary secretion. But nowhere is it shown that it has the slightest effect on the nerves. Yet we must believe that it does have much effect, or discredit a very large percentage of medical advertisements in the daily press.

We are prepared to take a most impartial view of the situation, and will be glad to learn that celery has powerful therapeutic effects in various directions. But we protest that the burden of proof is with the populace and not with the professors. At present all that medical

science can say is that celery is an agreeable weed to eat when cold and white and crisp and clean. Indeed, it seems a pity to put it into a tincture and grade it down with sarsaparilla.

TRANSPORTATION OF THE INSANE TO HOSPITALS.

While reform in the care and treatment of the insane, during the past decade or two, has been rapid, and, in some respects, radical, the manner in which they are carried to hospitals has received but little attention. In this State, for some time past, a mild under-current has been running in the direction of reform in this matter, but so far but little good has been accomplished. The time came long ago, when the insane person should have been differentiated absolutely from civil offenders; but as a matter of fact, the two are sadly confounded to-day by many persons who have to do with the insane in one way or another.

The reason of this is perfectly plain. When a person becomes insane (and we are speaking now of persons in the humbler walks of life, who cannot afford private attendance and skilled nurses), he promptly falls into the hands of the local constabulary or police, and especially does he meet this fate if he manifests the least tendency to disturb the public peace, or in any way show violence. Dr. Stephen Smith, in a very able paper entitled "More Rational Treatment of the Insane," that appeared in the *American Journal of Insanity*, January, 1894, says: "When a person is alleged to be insane, our laws place him in the category of persons who have been accused of civil offence. In many of the States the term, 'The Accused,' is employed in the statutes when such a person is referred to. This feature of our law is a relic of the old method of arresting the violent and disturbed insane under the common law of England."

We need not attempt to portray the ill-treatment often received by the insane, man or woman, at the hand of these ignorant and harsh petty officers of the law. Too often they are manacled, or laced in a straight jacket, put in prison, and fed on prison food, or not fed at all, if, by reason of some delusion, they refuse to eat. The grossest of indignities, however, is left for them to suffer when in process of transportation to the hospital to which they have been committed for care and treatment. The superintendent of a hospital for the insane in a neighboring State recently described the manner in which an insane woman was brought to the hospital, as follows: "She was brought twenty miles or more (in a wagon) in a drygoods box. The box was just large enough for her to sit in, and this had a blanket thrown over it, and tacked all around. Ropes had been placed on the sides to form handles. She had not been taken out of the box, and had not been able to change her position from the time of starting until she reached the hospital, several hours. Imagine the condition in which I found her when I tore the blanket covering off." In the same State, not long since, a man was carried half a day's journey to the hospital, strapped hard and fast to the top of a coffin. He was in this excruciating position for many hours. When released in the hospital he could not stand or move hand or foot.

It is difficult to give credence to the two instances cited above, but the fact of their occurrence is vouched for by a correspondent in whom we have every confidence. Of course, those in charge of our public hospitals have absolutely nothing whatever to do with the manner in which patients are brought to them. Their jurisdiction begins only when the patient has crossed the threshold of the hospital door. There would certainly appear to be room for reform in this direction.

CEREBRO SPINAL MENINGITIS.

During the past year cerebro-spinal meningitis has been epidemic in several localities in this country, and among them in New York City. Dr. Henry W. Berg has made a clinical study of this latter epidemic (*Archives of Pediatrics*), and a discussion of his paper took place at the Academy of Medicine in April. The disease was also seriously epidemic in Maryland, and at the instance of the State Board of Health, an investigation of it was undertaken by Drs. Simon Flexner and L. F. Barker, of Johns Hopkins University (*American Journal of the Medical Sciences*, February and March, 1894).

Dr. Berg shows that the mortality from cerebro-spinal meningitis in New York City rose from 230 in 1892 to 469 in 1893. The majority of the cases occurred in persons under the age of five, and there was no especial difference between the sexes. The greatest mortality occurred in May, but as the disease took a somewhat chronic type, it is assumed that it was actually most prevalent during the late winter and early spring. Attention is called to the fact that the epidemic followed in a measure the wake of the influenza, and corresponded with a great prevalence of pneumonia, facts which have been observed before. There seems to be nothing in the New York epidemic to point to cerebro spinal meningitis as distinctly a filth disease, nor were there any evidences that it is ever contagious. The cases on the whole, ran a very chronic course, and there were few instances of the *foudroyant* type of the disease. The attacks began with a chill and fever or with convulsions, often accompanied by propulsive vomiting and headache. Very soon the characteristic symptoms of pain and rigidity in the back of the neck, with muscular tenderness and pain, appeared. As a rule, there was a herpetic eruption on the skin, and nasal catarrh was frequent. As the disease progressed, symptoms of irritation and compression of the brain and cord developed, delirium, photophobia, pupillary and retinal changes, ptosis, strabismus, and other paralyses appeared, ending finally in stupor.

In discussing the pathology of cerebro-spinal meningitis, Dr. Herman M. Biggs was positive in stating that the disease presented no distinctive bacteriology or etiology. Cultures are sometimes sterile, or bacteria of various kinds may be found. The pneumococcus of Fränkel is oftenest present, and after this the streptococcus and the staphylococci albus and aureus. Dr. Biggs also asserted that cerebral meningitis was always cerebro-spinal, and that there were no facts to warrant a separation of the two diseases.

Dr. Biggs's views are not in accord with those of Drs. Flexner and Barker. These gentlemen say that the epidemic and sporadic cases of cerebro-spinal meningitis are due to a particular micro-organism, the micrococcus lanceolatus, discovered by Eberth in 1880, and by

Wechselbaum in 1886. This microbe is considered to be the cause of those forms of meningitis developing epidemically or in association with pneumonia. There is, however, another class of cases in which it is caused by injuries, or appears in the course of other infections such as typhoid fever, arthritis, sepsis, etc. Drs. Flexner and Barker report cases which corroborate their view.

MEDICINE AND MODESTY.

The *Cincinnati Lancet-Clinic* insists that the medical profession is just as big as any other calling, perhaps bigger. And it wants a medical cabinet officer at Washington right away. It says: "To-day the success of the army and navy is more dependent upon the resources of the medical department of those branches of national service than ever before." There is a little anti-climax here, though the statement will not be disputed. But our contemporary continues, with access of emphasis: "Very much of the efficiency of the Interior Department is dependent upon its medical staff. The finances of the country are at the mercy of medicine, while the prosperity of all the people is wholly determined by their condition of health."

This we think is really putting it rather strong. We yield to no one in appreciation of our calling, but it seems to us that the prosperity of our country depends on the ingestion of adequate food, the observance of law, and the prosecution of our industries, as well as upon sanitation. Let us insist on acknowledgment of our true merits, and upon the high functions which public medicine fulfils. They are of sufficient weight without the adventitious trappings of an expansive fancy such as our esteemed Cincinnati contemporary seems to possess.

But let us look at what our country needs first, and our professional advancement later. The country would be benefited by a national control of matters of public health. This can be gotten best by not asking at the same time for a cabinet officer.

PROFESSOR WILLIAM JAMES'S PLEA FOR THE MIND-CURERS.

Professor James, after denying that he holds any brief for the "healers," makes this extraordinary plea:—He says: "The facts are patent and startling; and anything that interferes with the multiplication of such facts, and with our freest opportunity of observing and studying them, will, I believe, be a public calamity. The law now proposed will so interfere, simply because the mind-curers will not take the examinations. They return to science disdain for disdain; and nothing will please some of them better than such a taste of imprisonment as might, by the public outcry it would occasion, bring the law rattling down about the ears of the mandarins who shall have enacted it.

"And whatever one may think of the narrowness of the mind-curers, their logical position is impregnable. They are proving by the most brilliant new results that the therapeutic relation may be what we can at present describe only as a relation of one person to another person; and they are consistent in resisting to the uttermost any legislation that would make 'examinable' information the root of medical virtue, and hamper the free play of personal force and affinity by mechanically imposed conditions."

The mind-curer has surely an eloquent advocate in the Harvard professor. But no one except those daily familiar with the aspects of disease can understand how specious and silly such talk is. First, let us ask where are the "facts" that are so "patent and startling." Is there a single disease in our nosology which the "healers" heal in larger percentage than does rational medicine? What are the "facts" about pneumonia, fevers, phthisis, cancer, rheumatism, and all the familiar forms of suffering which the physician meets and relieves daily? Let Dr. James put a "healer" in charge of the medical ward of a city hospital and see how "the impregnableness of a logical position assists him in pulmonary œdema or a failing heart. If there are "brilliant new results," why are they not collected, authenticated, and presented to the world in a way that will bear honest inspection? At present they are simply rumors that pass from one fanciful female or over-credulous psychologist to another, and have about the evidential value of the ghost stories accumulated by the Phantom Committee of the Society for Psychical Research.

The medical profession knows well how much its art is limited, and eagerly accepts any genuine help. But it has no evidence that mind curers do more than amuse the leisure of selfish invalids and nurse the introspections of feeble philosophers.

News of the Week.

The Escape from the Electric Chair.—Governor Flower has wisely respited Mrs. Halliday, the Monticello woman recently convicted of murder in the first degree and sentenced by the judge to death in the electric chair. The commission of experts appointed to examine into her sanity reported that she was of unsound mind. In view of the evidence, even on the trial, there was no other conclusion to be drawn. The sentence was accordingly changed to imprisonment for life as an insane convict. The Governor is to be congratulated on his fairness and good sense. The Governor of Illinois might have done the same for Prendergast and with equal propriety, but it is now too late, as it is with other things he left undone.

Brooklyn last week had the extraordinarily high death-rate of 33.4 per 1,000.

Dr. Joseph Pagani, of Boston, died on July 15th. He had practised in the North End for twenty years. He was born in Borgomanero, Italy, in 1836. In 1863 he was graduated from the University of Pavia. He came to America in 1865, and after a short stay in New York went to Boston. For his kindness to Brazilian subjects he received, in 1882, from Dom Pedro the decoration of Chevalier de Buenos Ayres. In 1892 he was made Cazique and Baron Hoxley in the Aryan peerage of Russia. He was a distinguished member of several medical societies, among which were L'Académie Médecine of Paris and the Societa Medicale di Roma.

Dr. John Williams, who attended the Duchess of York during her recent confinement, has been created a baronet.

Professor Hermann Helmholtz was taken suddenly ill on July 12th, with a brain lesion and now has left-sided hemiplegia.

The Plague in Hong Kong is reported to be subsiding, but cholera is on the increase in Canton.

Monuments to Medical Men.—The work of securing funds for a monument to Professor Charcot is progressing favorably, and is receiving help from Germany and other countries. A monument in memory of the great Russian surgeon, Pirogoff, will shortly be erected in Moscow. The subscriptions for this object already amount to 12,000 roubles (about $6,000). The monument will appropriately be placed on one of the open places between the blocks of the immense new clinique in Moscow.

Texas Not the State for a Young Doctor.—A correspondent writes that he left New York to verify the well advertised chances for the young medical man in Texas; but after travelling throughout the entire State he found every place more than full, with not a few waiting for chances to earn money enough to get home. He says there is even a better chance in New York.

The Immediate Repair of the Permanent Cervix.—Dr. H. D. Gardner, of Scranton, Pa., writes: "In the article of July 7th on the 'Causes of Diseases Peculiar to Women,' you say lacerations of the cervix and perineum should be repaired early. Now I, in common with many others, believe in the immediate repair of the perineum; I have never tried to repair the cervix, but think it might be done, and in order to do this you must first find the tear. Now I know of no way so good as to look for it. Turn down the bedclothes and with a good light, lamp or candle, look and see whether there is a tear or not. No power on earth could prevent it, but you can repair it easily and quickly. I look upon this as the most important duty of the obstetrician."

Bequests to Hospitals.—The late John Crerar, of Chicago, has bequeathed to the Presbyterian Hospital of this city $25,000; to St. Luke's Hospital, $25,000.

Medical Legislators and Medical Mayors abound in France. The first to go to the aid of the murdered President Carnot was Dr. Gailleton, the Mayor of Lyons. Among the leaders of the medical section in the French Parliament are Professors Cornil and Lannelongue and Dr. Léon Labbé. These gentlemen, says *The Lancet*, recently convened a meeting of their fellow (medical) members, and the outcome of the conference was the formation of a medical group, whose duty it shall be to watch over professional interests in the two houses. M. Labbé was appointed President, and MM. Cornil and Lannelongue vice-presidents of this new group. The freshly formed party has already begun work, for it has discussed a bill introduced by M. Labbé which, if adopted—and it has every chance of being carried—will prolong the limit of age of medical students, with regard to their military obligations, from twenty-six to twenty-seven years.

Death of the Smallest Man in the World.—Dudley Foster, said to have been the smallest man in the world, died at Bridgetown, N. S., on June 20th, of heart disease, aged sixteen years and ten months. He was thirty inches high, and weighed twenty pounds.

Anticholera Inoculation.—An Indo European telegram states that within the previous few days three further remarkable instances of the success of M. Haffkine's system of anticholera inoculation had occurred at Calcutta. In the first case four out of the six members of a family were inoculated last March. The cholera appeared in the neighborhood lately, and the disease attacked one of the two who had not been inoculated, while the inoculated remained free. In the second case, five members of a family consisting of eleven persons were inoculated in March. The cholera lately attacked one of the six who had not been inoculated. In the third case, six out of a family of nine were inoculated. When the cholera prevailed in the neighborhood a few days later the disease attacked one of the three not inoculated. The Corporation of Madras have passed a resolution inviting M. Haffkine to visit that city and introduce his system.

Sir Joseph Lister.—The Council of the Society of Arts has, with the approval and sanction of the President, His Royal Highness the Prince of Wales, awarded the Albert Medal to Sir Joseph Lister "for the discovery and establishment of the antiseptic method of treating wounds and injuries, by which not only has the art of surgery been greatly promoted and human life saved in all parts of the world, but extensive industries have been created for the supply of materials for carrying the treatment into effect."

Sterilized Milk is becoming a popular hot-weather drink in this city.

A Political Honor to a Physician.—An esteemed correspondent writes from San José, Costa Rica, to inform us that Dr. Juan J. Ulloa, who was a delegate from Costa Rica to the Pan-American Medical Congress, and who is a graduate of the Medical Department of the University of the City of New York, has been appointed Secretary of State in the Departments of the Interior and of Public Improvements of Costa Rica.

Dr. V. P. Gibney has been elected Professor of Clinical Surgery in the College of Physicians and Surgeons of New York City.

Prize for an Essay on Tuberculosis.—At the Denver meeting, just closed, of the Colorado State Medical Society, the following resolution, offered by Dr. Denison, was carried, and Drs. Charles Denison, H. A. Lemen, and S. E. Sally were appointed as such Examining Committee: *Resolved*, That this Society offer a prize of $100 for the best essay upon the following subject: The Diagnosis of Tuberculosis by Microscopic Examination of the Blood.

Asparagus.—English journals have been actively discussing the physiological action of asparagus. The conclusion reached is that it is a diuretic.

The Caul still seems to have a commercial value. Witness the following advertisement in a New York daily: "Caul for Sale, reasonable. Address ———, box ——, *World*, uptown."

The American Electro-therapeutic Association will hold its fourth annual meeting in New York on September 25th, 26th, and 27th, at the Academy of Medicine. Members of the medical profession are invited to attend.

Society Reports.

Congress of American Physicians and Surgeons.

Third Triennial Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

AMERICAN GYNECOLOGICAL SOCIETY.

Nineteenth Annual Meeting, held at Washington, May 29, 30, and 31, 1894

(Continued from Vol. 45, page 769.)

SECOND DAY, WEDNESDAY, MAY 30TH.

President's Address.—DR. LUSK chose for the subject of his address "The Proper Position of Recent Surgical Methods in the Treatment of Uterine Fibroids." There is nothing, he said, which in an equal degree marks in gynecology the boundary line between the old order of things and the new, as the recent discussion upon the surgical treatment of uterine myomata. Myomata might remain of small size and produce no symptoms. When small and the symptoms were slight, the surgeon could delay a little and control attending menorrhagia by curettage, etc. The argument in favor of more radical measures because of the supposed liability of myomata to malignant changes, especially in patients nearing the climacteric, clinically had not much weight.

Gottschalk, Franklin, Martin, and others had had favorable experience in controlling the symptoms and growth of uterine fibroids in certain cases by tying the uterine arteries through the vagina. It seemed to the President unwise bigotry to ignore such testimony because ligation of the uterine arteries belonged to the domain of little things. Certainly the patient would prefer to be relieved in that way to having the uterus removed.

It was a question whether sufficient attention had been paid in this country to the large amount of efficient work that had been accomplished abroad in connection with the enucleation of fibroids by the vaginal passage.

Chrobak alone had reported forty-three cases, with but one death. The tumors were cervical, submucous, and interstitial, and varied in size from a child's head down. The President related one of his own cases of this kind, in which able men had said the tumor could not be removed except by opening the abdomen. After enucleation, entire or by morcellement, the uterus or cervix could be restored by plastic operation. It might seem a little thing, but women would prefer not to have the scar left by abdominal operation, and the danger of hernia was shown by the fact that, at Jacob's clinic, in 259 cases hernia occurred in 38. By the vaginal method better drainage was secured, and there was less shock. The results by the vaginal method were remarkable—Péan, 300 cases with only six deaths; Richelot and Doyen together, 88 cases with two deaths. When the tumor exceeded in size a child's head experience taught that, as a rule, it was advantageous to attack it from above.

Regarding castration for control of symptoms pertaining to fibroids the views of Martin, Leopold, Gusserow, Lawson Tait, on their statistics, were quoted to show that often the procedure gave a satisfactory result. Castration, however, was no longer advocated in large tumors and cystic tumors.

In all cases where the abdomen had been opened, the possibility of saving the uterus and appendages should not be lost sight of. All pedicled growths should be tied and removed.

The views of Polk and Martin, particularly, were referred to in the line of sparing the healthy tissue where it was necessary to remove disease of structure in the uterus and appendages. There would still, however, remain a certain number of cases in which, owing to the size of the tumor, cystic degeneration, number of growths, etc, it would be necessary after opening the abdomen to do total extirpation.

Dr. Lusk then passed to a consideration of methods of treating the pedicle. Although good results had been obtained from fastening it into the abdominal wound, the method had been abandoned; some patients returned with a fistula, etc. Complete removal and amputation, leaving the lower cervical segment only, were methods advocated by the best authority.

Discussion was then called for upon the papers of Drs. Lusk, E. C. Dudley, and Wathen.

DR. W. M. POLK thought also there could be no one method applicable to all cases of uterine fibroids. He favored conservative measures, retaining healthy structures, wherever removal of simply the diseased portions would be likely to terminate in cure. This remark was especially applicable in disease of the appendages, for even pus in the tubes did not necessarily preclude ovulation.

DR. BALDY thought that if myomectomy was to be done at all, it should be by the abdominal, not by the vaginal, method. It was, however, attended by danger of hemorrhage, sepsis, and recurrent disease.

DRS. CUSHING and GORDON also advocated total removal of the uterus, as opposed to myomectomy.

DR. W. GILL WYLIE believed in suiting the operation and the method of performing it to the particular case, and thought the President's paper presented the subject very justly.

DR. BYFORD expressed similar views, and Dr. Engelman regretted that some of the gentlemen had seemed to show prejudice against attacking any cases of fibromata uteri per vaginam, regardless of their size.

DR. A. P. DUDLEY related a few cases illustrative of the advantage of the different procedures under different circumstances.

Rupture of the Uterus; Palliative versus Surgical Treatment.—The discussion upon this subject was opened with a paper by DR. CHARLES M. GREEN, of Boston. He said: It is improbable that any authority at the present time would advocate any specific treatment as applicable alike to all cases of rupture of the uterus. The object of the discussion is rather to arrive at the methods most suitable for particular classes of cases, according to the condition and situation of the patient, the availability of surgical skill, the site and character of the rupture and manner of its production, the extent to which the child has escaped into the peritoneal cavity, the presence or absence of hemorrhage, the condition of the uterus as regards sepsis.

Surgical treatment should embrace, not alone laparotomy, with or without suture of the rent or removal of the uterus, but also the various methods of drainage with gauze, wicking, or tube, with or without antecedent irrigation; while palliative treatment included the various general therapeutic measures for sustaining the patient, relieving pain, and combating shock, combined with local antisepsis and natural drainage. The two were often advantageously combined.

To one with limited experience in abdominal surgery and severer obstetrical practice, the idea of laparotomy after rupture of the uterus was an attractive one, but extended experience could but convince that in many cases less radical measures gave better results.

Merz's statistics of 230 cases, grouped under ten heads, were given. Complete rupture, 181 cases, with 63 recoveries; incomplete rupture, 46, with 19 recoveries.

Dr. Green divided the cases of uterine rupture for purposes of treatment into three classes: 1. Complete or incomplete tears of the lateral or posterior walls of the lower segment, with adequate provisions for vaginal drainage, hemorrhage easily controlled, no intestinal hernia; such cases often recovered under palliative treatment, drainage, and antisepsis. 2. Complete tears of lower segment, or moderate tears of uterine body, more or less blood-clot, etc., having entered the peritoneal cavity; treatment might be by peritoneal irrigation and drainage

with gauze. 3. Cases in which extraction of child through pelvis is impossible or inexpedient, hemorrhage uncontrollable per vaginam, rent extensive, irrigation, transverse, or ragged; in such cases abdominal section is indicated. The propriety of suturing the rents must be decided according to the condition of the uterus and the edges of the tears; when the latter are very ragged and infiltrated with blood, when the uterus is friable and apparently septic, hysterectomy promises better results than suture.

The Palliative Treatment of Rupture of the Uterus — Dr. Malcolm McLean, of New York, read a paper with this title.

One of the most constant and characteristic phenomena connected with rupture, the author said, was sudden recession of the presenting part. After strongly protesting against one allowing himself to be led by modern radical tendencies in surgery to operate in all cases of rupture of the uterus regardless of the particular conditions present, the field for palliative measures was pointed out and an illustrative case cited. The hand was introduced, the child was found, escaped through a rent in the right anterior wall of the uterus, so that only the head and right arm were within the uterine cavity. In examining the edges of the wound it was noticed that the surfaces were completely shielded by the amniotic sac, which was pushed through ahead of the limbs of the child, forming a hernial sac into the peritoneal cavity. Without any difficulty the child was drawn back into the uterus and at once delivered by the feet. The placenta with the membranes were withdrawn, and a considerable quantity of amniotic fluid, meconium, etc., was brought away in the pouch of the amnion which had protruded through the rent in the uterus. Believing that the peritoneal cavity, therefore, had not been invaded except by purely blood extravasation, the case was left to nature, using, of course, antiseptic douches, etc. The woman made a good recovery after a somewhat tedious convalescence while absorbing a considerable hæmatocele in the right side of the abdomen.

A year and a half later Dr. McLean delivered the same patient, and the cicatrix was distinctly felt through her very thin abdominal parietes.

Stress was placed upon the fact that the amniotic sac had protruded into the rent and protected infection of the peritoneal cavity.

The President, Dr. Lusk, being requested to speak, said he believed that all reported cases of rupture of the uterus through the anterior wall had terminated fatally. When the rupture was complete, but the child only partly extruded, a small proportion of the mothers had recovered under vaginal extraction and subsequent drainage, but unfortunately nearly all of them had afterward been hopeless invalids. Therefore, if the rupture were completely into the abdominal cavity, and the woman was not moribund, he would feel safer on returning home if he had opened and cleansed out the abdomen, and either sewed up the rent or removed the uterus according to the case.

Dr. Reynolds, of Boston, would not agree with the President that patients who recovered after palliative treatment were hopeless invalids, as out of four cases of rupture of the uterus seen by him only one died, three recovered, and, under palliative measures were healthy subsequently.

Dr. E. C. Davis thought the thick uterus in multipara which had ruptured was likely to be friable, very susceptible to infection, offering little hope of union by suture; therefore removal of the organ seemed preferable.

Dr. W. M Polk said he felt, when brought before a case of rupture of the uterus, that he was between the devil and the deep sea—that is, death of the patient from sepsis if he did not operate, and death from added shock if he did. Usually there was already a state of collapse which forbade a formidable operation. Owing to the fact that operations per vaginam caused not more than a third the amount of shock attending approach by the abdomen, one should, if possible, ligate the vessels from below, and close the lower uterine rent at least, or perhaps do hysterectomy from that direction.

Dr. R. W. Murray, of New York, related four cases of rupture of the uterus, the last one seen with Dr. Coe—profound shock, laparotomy, death. This case showed that removal of the uterus (which was not undertaken) might prove extremely difficult, if not impossible, owing to the great thickness, œdema, and vascularity of the tissues. Two cases seen in private practice recovered under palliative treatment. If there was no doubt of rupture into the abdomen he thought it best to resort to cœliotomy.

Third Day, Thursday, May 31st.

The Influence of Laceration of the Perineum on the Uterus and the Operation for its Repair.—Dr. W. Gill Wylie, of New York, made the following points in this paper: The main forces which act on the contents of the abdomen are the muscles, the diaphragm playing the principal part. When we wish to keep the abdominal contents quiet, the diaphragm and abdominal muscles are contracted. The axis of the uterus is normally in line with the forces bearing upon it from above. When it is displaced backward or forward those forces strike it broadside and act much more powerfully in displacing it. The axis of the rectum is at right angles to that of the anus, so that when the rectum is full it shuts the anus. The force which most influences the pelvic organs is straining at stool. The perineum tends to keep the anus in shape with relation to the rectum. Destroy the perineal support of the rectum and the straining at stool will force the rectum forward, carrying the vaginal walls before it, producing so called rectocele. In repairing the perineal injury Dr. Wylie made it one of the special objects to tilt the so-called rectocele backward and bring up the depressed sulci, or angles on either side over the rectocele. It differed from Dr. Emmet's operation in one regard at least, that is, the area of denudation was solid, whereas in Emmet's a central portion was left undenuded. The external sutures, extending to the normal place of the hymen, did not exceed four in number, the internal or those above that point being about the same in number and of silver wire. They were left in three weeks, in order to give full time for union to occur in the white fibrous tissue where the lesion had existed long enough for muscular fibres to disappear. If the central portion of the area of denudation were left untouched it would not prevent return of the rectocele. Where there was rectocele there were also hæmorrhoids; hence the necessity for treating these and of stretching the rectum, a procedure which he believed was commonly omitted, accounting, in part, for many failures.

The paper was discussed and criticised by Drs. Noble and Skene. The latter thought no one procedure adapted to all kinds of tears.

The Ultimate Results of Retro-displacement of the Uterus by Pessaries, with Special Reference to Alexander's Operation.—Dr. Francis H. Davenport, of Boston, read this paper. The conclusions reached were, that in cases of uncomplicated retroflexion or retroversion the choice of treatment lay between the use of the pessary and shortening the round ligaments. Where the former was decided upon a cure could be expected in about twenty-five per cent. of the cases. Where a cure was effected by pessaries it was usually within a year or a year and a half after beginning treatment. A large proportion of the patients not cured could still wear a pessary without discomfort and did not wish an operation. The Alexander operation should be limited to those cases in which a pessary could not be worn and those preferring it to the support; to cases in which vaginal support was inappropriate; also as supplementary to other operations.

Dr. Cushing thought the paper a very judicious one, although he must differ from some of the conclusions, He did not think statistics upon cures effected by pessa-

ries of any value in the past. He believed with the reader, that there were few cases of backward displacement which could not be rendered quite comfortable or cured by pessary, or else there was a complication which rendered treatment by the Alexander operation inappropriate—usually some adhesive band. Therefore in a large proportion of cases where pessaries were not successful it was best to open the abdomen and discover the cause, rather than do Alexander's operation.

Dr. Clement Cleveland had had very good success with the retroversion pessary. If a permanent cure could be effected by it, it would usually take place within a year. At the end of that time he allowed the patient to decide whether she preferred an operation, and if the case were a suitable one and the round ligaments were shortened by a correct procedure success would follow in at least seventy-five per cent. of the cases.

Dr. G. M. Edebohls, of New York, had had less success in the cure of backward displacements of the uterus by pessaries than had been claimed by some other gynecologists, and since his success with shortening the round ligaments by the method employed by him had been practically uniform he always resorted to this or else let the patient go elsewhere for treatment by the pessary. A number of these had returned, having tired of wearing the support although it gave no special discomfort; then shortening the round ligaments, he had sent them away permanently cured. Of course he was assuming that the cases were suitable ones for treatment by either of these methods.

Dr. Gehrung thought the percentage of cures by pessary was greater than had appeared from statistics, for the reason that, when recurrence of the displacement had taken place some time after leaving off the use of the pessary, the case had always been placed among the failures, whereas it might in reality have been a cure with recurrence due solely to renewal of the cause. While the pessary might not give that positive result produced by fixation, it was at least free from the unnatural state left by this.

Dr. Dickinson, of Brooklyn, impressed the fact that a permanent cure of uterine displacement could not be expected so long as women continued their faulty modes of dress and occupations which involved an unnatural position of the body, especially of the abdominal and pelvic organs, and destroyed muscular tone.

Inflammation of the Ureters from a Medical Standpoint.—Dr. M. D. Mann, of Buffalo, read a paper, considering in a systematic manner inflammation of the ureters, its pathology, causation, treatment, etc. His knowledge of inflammation of the ureters began only a few years ago when Dr. Kelly, of Baltimore, called attention to the condition; while the disease was still scarcely mentioned in the text-books, he believed it was common and was of great importance. Among the causes he first mentioned injuries during childbed and related a case. Of ascending ureteritis from bladder trouble, he had never seen a case except of gonorrhœal origin. Yet gonorrhœal cystitis in women did not often attract attention. It was probable that it might lurk in the ureters after it had ceased in the bladders, for the reason that treatment was commonly limited to the bladder in gonorrhœal inflammation which had extended to this organ or higher. Dr. Mann did not doubt but what failure to relieve pain after cœliotomy was often due to unrecognized gonorrhœal inflammation of the ureters. Where the ureteritis was due to inflammation extending downward, the cause, according to his experience, was nearly always the presence of renal calculi or renal tuberculosis. He believed that symptoms attributed to pressure upon the bladder by displacement of the uterus were commonly due to an abnormal condition of the urine and its influence upon the ureters.

Pressure was recognized by all writers as a cause of ureteritis, and the author thought no one would doubt but what a fibroid tumor of the uterus, an ovarian tumor, and even cancer of the uterus might exert sufficient pressure upon the ureters to cause inflammation. But an abnormal condition of the urine was, in the author's opinion, the cause of the great majority of cases. In many the urine was excessively acid and also scanty. While containing a variety of crystals, the total solids were apt to be below normal. It was sometimes called the condition of lithæmia, and was frequently brought about by reflex neurosis affecting the digestive organs, and sometimes by certain foods, strawberries being among those which acted obnoxiously in some people. Tuberculosis of the ureters had been occasionally recognized.

The diagnosis rested upon the symptoms, the examination of the urine, which should be chemical and microscopical, and upon palpation and inspection. In many instances the ureters could be felt thickened, and on inspection, which could easily be made by Kelly's method, in the area about the vesical openings of the ureters might be found the seat of granulations or ulcers, irritation of which by the abnormal urine caused vesical tenesmus.

The treatment was constitutional, local, and symptomatic. Constitutional treatment was specially important. Diet should be corrected, the urine should be rendered alkaline and increased in quantity, and diaphoresis induced at the beginning. Sandal wood had had a valuable influence through the urine, also some other agents often given internally in gonorrhœal urethritis. As to surgical treatment, the author had a few times catheterized and dilated the ureters, but without special result. Granulations about the mouth of the ureters could be treated locally. Ureteritis was apt to affect both canals, but one more than the other.

Drs. Baldy, A. P. Dudley, Willis Ford, Cushing, and the author participated in the discussion. Dr. Baldy had seldom found ureteritis, and thought it must be a rare condition.

Symphyseotomy Versus the Induction of Premature Labor.—Dr. C. P. Noble, of Philadelphia, read this paper. Three questions were propounded: 1. Is embryotomy upon the living child and deliberately selected a justifiable operation? 2. Is it justifiable in labors not among cases of contracted pelvis, yet in which there is considerable obstruction making such violent efforts at version or forceps necessary as to threaten mother and child, instead of resorting to symphyseotomy? 3. In contractions of moderate degree is it better to induce premature labor sufficiently early to permit of bringing forth a living child, or to let pregnancy go to term and resort to symphyseotomy, should this prove necessary?

Regarding the first question, craniotomy on the living child, Dr. Noble thought it had been answered in the negative. The problem was not to save the mother alone, but to save both mother and child by a procedure which gave hope of diminishing the mortality of both to that of the mother alone where craniotomy was resorted to. Dr. Noble also thought the second question would in the future be answered in favor of symphyseotomy, but he did not pretend to express anybody's opinion but his own.

In answering the third question it was necessary to consider the mortality of mother and child in premature labor compared with that in symphyseotomy. The general mortality to the mother in premature labor had been given as five per cent.; in symphyseotomy as ten per cent. Dr. Noble believed, that in both the figures were entirely erroneous. Five per cent. was undoubtedly too high a maternal mortality in induction of premature labor for contraction; it should not be higher that one per cent. in good hands. Ten per cent. mortality for the mother under symphyseotomy was also entirely too high, as it represented the results in all cases, and it was well known that the operation was likely to be put off until the mother was in very bad condition from use of forceps, etc. In order to compare the safety of the two procedures only those cases of symphyseotomy should be included in which it had been an elective operation, resorted to before injuries had been inflicted by forceps,

etc. The maternal mortality from symphyseotomy under favorable circumstances should be very low. The advantages to the child over premature labor were striking, for many premature children died at birth, and many more succumbed afterward. The author narrated a case which he had reported before, the first one in the world in which symphyseotomy had been resorted to in preference to premature labor, and the first one in the United States in which the patient had submitted to a second symphyseotomy at a subsequent pregnancy.

The views of the author were substantially agreed with by Drs R. W. Murray, Charles Jewett, Engelman, and Malcolm McLean.

Officers: Dr. M. D. Mann, of Buffalo, was elected President; Dr. H. C. Coe was re-elected Secretary. The date of the next meeting will be the fourth Tuesday in May, 1895. Place yet to be decided upon.

AMERICAN SURGICAL ASSOCIATION.

Fifteenth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from Vol. 45, page 800)

THIRD DAY, THURSDAY, MAY 31ST.

The Surgical Treatment of the So-called Surgical Kidney.—DR. R. F. WEIR, of New York City, read a paper on this subject. He reported the case, he said, in order to show that the prognosis is not always as bad as we hitherto thought it. The case was that of a young man who had an attack of pneumonia some four years ago, followed by scarlet fever and nephritis. Albumin and casts persisted, and he never regained his health.

Two months ago he had an attack of urethritis. Gonococci were present in great numbers. It subsided under treatment of creoline, silver nitrate, and zinc sulphate solution. Twelve days prior to his admission to the hospital, without any assignable cause, he had a chill, preceded by a temperature of 101° F., with vomiting and diarrhœa. The next day he had pain in the loins, which was thought to be lumbago, but on the next day there was great tenderness over the right kidney.

During the seven days between his admission to the hospital and the operation, he had four chills, with temperature ranging from 103° F. to 105° F., pulse 116 to 120. He passed fifty to sixty ounces of urine daily. It contained pus. It was thought enlargement of the right kidney could be made out, but I thought it was an abscess. I did not think he had the ordinary condition known as the surgical kidney.

Operation.—An incision was made and the kidney exposed. It was twice its ordinary size. It was deeply congested and swollen, particularly on its inferior surface. Puncture with the aspirating needle gave no indication of pus, but an incision revealed the nature of the disease. It disclosed numerous miliary abscesses. The kidney was rapidly removed and the wound packed with iodoform gauze.

Result.—Immediately after the operation the temperature dropped from 105° F. to 99° F., and then remained subnormal for a few days. The patient made a rapid recovery, and was discharged from the hospital three weeks later. At the time of his discharge the urine was nearly normal, and no treatment was advised beyond spending as much time in the open air as possible.

How often Does such Unilateral Renal Trouble Exist?—The first question this case would naturally suggest to all surgeons, is how often may such a fortunate condition of affairs be found in cases of surgical kidney? That this form of nephritis is sometimes limited to one kidney, is beyond doubt. The statistics of one man show that out of one hundred and thirty cases of surgical kidney, nineteen were unilateral. From the hospitals of New York, out of seventy-one cases of miliary abscess, both organs were affected in fifty-nine, and only one organ in twelve cases, or about twenty per cent. of these cases, might have been treated successfully.

Future Prognosis.—The speaker could not help feeling more hopeful in the treatment of these cases than in the past. Even where both organs are involved, something should be done in the way of evacuating the pus. Where the patient's condition warrants it, and especially when there are symptoms pointing to one side, it is justifiable to make exploratory incisions on one or both sides.

Surgery of the Ureters.—DR. CHRISTIAN FENGER, of Chicago, read the paper.

Discussion.—The papers read by Drs. Tiffany, Weir, and Fenger were discussed together.

DR. RICHARDSON, of Boston, said the examination of the urine prior to operation was most important, as it was often the deciding point in doing operations which were not absolutely necessary. In removing a kidney he would prefer to go through the abdomen, which gave you a better opportunity to avoid or control hemorrhage. The incision should be large enough to permit the examination of both kidneys. This would also avoid the danger, in unilateral trouble, of removing the only kidney the patient might possibly have.

DR. MUDD, of St. Louis, thought the low temperature and the quantity of urine passed to be a better indication than albumin or casts. He also thought as much of the kidney as possible should be saved, as the kidney had great reparative power; also, that it was disastrous to remove the kidney immediately after an injury, before the patient had recovered from the shock of the accident. He thought it was very difficult to determine by handling whether you had good kidney material or not. He did not approve of the abdominal incision, unless you were in doubt about the other kidney, as hemorrhage could be controlled just as well from behind.

DR. NANCREDE was opposed to the abdominal operation, owing to the danger of infection from the pus which might possibly escape into it. He insisted upon being sure the patient had two kidneys before removing one.

DR. CARMALT, of New Haven, said in searching for both kidneys you should bear in mind the abnormal positions which may exist. In one post-mortem case he found the left kidney low down in the pelvis, and in this case a possible mistaken diagnosis of one kidney might have been made.

The paper was further discussed by Drs. Prewitt, Deever, of Philadelphia; Gaston, of Atlanta; Fenger, of Chicago; and Forbes, of Philadelphia. The last-named gentleman exhibited an indigo stone weighing one hundred and forty-seven grains, with the interesting statement that the patient had no renal symptoms, showing an unusual tolerance by the kidney of such a large foreign body.

Treatment of Malignant Tumors with the Toxines of Erysipelas.—DR. WILLIAM B. COLEY, of New York, read the paper. He began this treatment of multiple sarcoma by repeated injections of living cultures of erysipelas streptococci in 1891, and gave the account of ten cases. Six were sarcoma and four carcinoma.

In four cases erysipelas was produced, but the marked improvement in the cases where erysipelas was not produced led the speaker to believe that the curative action was due to the toxines, rather than to the germ itself.

In 1892 he experimented with bouillon cultures prepared by heating to 100° C., and the effect was slightly less than when living cultures were used.

Early in 1893 he began using cultures filtered through porcelain without subjecting it to heat. The toxines of the bacillus prodigiosus prepared in the same way were used in conjunction with the erysipelas toxines which intensified the action of the erysipelas toxines on the sarcoma, and was much more effective than that of the erysipelas toxine alone.

Toxine Must be Fresh.—The toxine to be of value must be freshly prepared from very virulent cultures. All successful cases were from cultures made from fatal cases of erysipelas.

Results.—Of twenty five cases of sarcoma treated, six were cured without any recurrence; nine showed marked

improvement; eight, improvement slight; and two, no improvement.

Of eight cases of carcinoma, all but one showed more or less improvement, and in three cases the improvement was marked.

The diagnosis of all these cases was established by eminent surgeons and pathologists.

How do the Toxines Cure?—No rational explanation of the action of the toxines on malignant tumors can be offered, except on the assumption that such tumors are of micro-parasitic origin. Admitting this theory, explanation would be easy, viz.: antagonistic bacterial action.

The following were the conclusions of the paper: 1. The curative action of erysipelas upon malignant tumors is an established fact. 2. The action is more powerful upon sarcoma than carcinoma. 3. The action is chiefly due to the soluble toxines which may be isolated and used with safety and accuracy. 4. The action is greatly increased by the addition of the toxines. 5. The toxines, to be of any value, must be fresh and from virulent cultures. 6. The results obtained from toxines, without danger, are nearly so, if not quite, equal to those obtained from a fresh attack of erysipelas, and inoculations should rarely be resorted to.

Dr. Keen, of Philadelphia, had treated seven patients in the same way and manner, but in not one of these cases had there been even an arrest of growth. He had obtained reactions as high as 103° to 104° F., while in some cases no reaction took place. He injected in the tissues in some cases, and directly into the tumor in others.

In one case there was a breaking down of the growth, but when the use of the toxines was discontinued, the case went on rapidly. He had never seen any harm done further than the rise of temperature. As his experience with the toxines had been limited, he could not hope to obtain as good results as Dr. Coley.

Dr. Park, of Buffalo, had inoculated cases with erysipelas from patients in the hospital wards, without results. He got some culture from Dr. Coley, but the results were no better than those obtained by Dr. Keen. He thought it a case of different men working in the same manner and obtaining different results, the most experienced getting the best results.

Dr. Warren's experience was similar to that of Drs. Keen and Park, but thought the subject should be encouraged in every way, and conclusions should not be jumped at. The question of the character of the reaction he thought an interesting one. It was thought, where the injection was in the tissues, a fatty degeneration of the cells of the sarcoma took place, but when the tumor was injected it was a necrosis. It should also be remembered that all the cases were selected as inoperable.

Dr. Richardson stated that one of the successful cases was sent by him to Dr. Coley. In this case there was no doubt whatever about the nature of the disease, and without this treatment the patient would have died. The case was a perfect cure.

Venous Tumor of the Diploë was the title of a paper read by Dr. L. S. Pilcher, of Brooklyn.

History.—The patient, a girl, fifteen years of age, at the age of five, fell, striking on the top of her head. In a few days afterward a small, soft swelling appeared, gradually increasing in size, causing no pain or tenderness. At the end of five years it was lanced and a small quantity of blood evacuated. The swelling immediately refilled. It was lanced again in a few years afterward, with similar results. Nothing further was done until her admission into the hospital.

When admitted she presented a tumor over the anterior fontanelle. It was covered with a thin skin, devoid of hair, and of a bluish hue. It was soft and fluctuating, and diminished slightly under pressure. It had been enlarging and was on the point of bursting.

Operation.—On March 14th the tumor was incised. It consisted of a small blood-clot and fluid blood. The tumor was fed by several channels leading from the veins into it. Hemorrhage was controlled by pressure and tampons. The entire cavity was thoroughly curetted and tamponed with gauze, and the opening sutured.

The interesting feature of this case is the fact that it was not a dilatation of any blood-vessel, but a true traumatic tumor; being an adventitious blood-space fed by channels from the blood-vessels.

Strangulation of Meckel's Diverticulum.—Dr. J. W. Elliott, of Boston, reported the case. The interesting features were the symptoms presented by the patient, all of which pointed to appendicitis. Under manipulation a large, hard mass was felt in the abdomen. A vertical incision was made in the abdomen, and the appendix found to be normal, and the true nature of the trouble revealed. The patient subsequently died from septic peritonitis.

The paper was discussed by Drs. C. Fenger, of Chicago; Tiffany, of Baltimore; and White, of Brooklyn, N. Y. In the discussion attention was called to the fact that a tumor near the umbilicus should direct attention to the diverticulum.

The Removal of Stone in the Bladder.—Dr. W. S. Forbes, of Philadelphia, read a paper on this subject and presented a new lithotrite. Given the problem of a stone in the bladder, a limited viaduct through which to reach and remove it without injury to the parts, we have two unknown factors, viz.: the crushing resistance of the stone, and the strength of the lithotrite.

Crushing Resistance — How Obtained. — The exact crushing resistance of a stone has never been stated by any writer, except in vague terms, as tough, etc. The same may be said of the description of the strength of the lithotrite, as strong, powerful, etc., all of which mean anything and nothing.

In order to attain the necessary knowledge in the question, it is necessary to measure the crushing resistance of a large number of stones taken from the human bladder. The conditions of science should be weighed, as it were, in the fine scales of the jeweller. A very large number of stones were tested in the lithotrite, which was placed in and worked by a very powerful machine, so delicately and accurately constructed and adjusted that every ounce of force applied in crushing the stone was recorded.

The New Lithotrite has all of the elements contained in the Bigelow and Thompson, but the construction and general lines of it, however, are entirely original and widely different from any lithotrite now in existence. The penile and vesicle ends consist of a male blade sliding within a female blade and held within the latter by a slightly angular undercut slot. This prevents the male blade rising out of the female blade when under a strain. The greater the strain the tighter it is held.

The long axis of the shaft is straight to within two inches of the crook or curve, and here rises to an angle of about three degrees until it meets the curve. This accomplishes six important objects: easy introduction of the instrument over the urethra; increases strength of female blade by giving it support higher up; allows a larger stone being grasped without incurring a longer female blade; places the metal of the female shaft where it is most needed; prevents side movement or twisting of the male blade by giving it a deeper slot to move in, thereby supporting it higher up; the angle between the female blade and the long axis of the shaft is the same as if the shaft was straight all the way to the curve; the female blade has its proximal surface concave and prevents calculus slipping out when the power is applied, and tends to give strength to the instrument; it is elliptical and uniform in size to within three inches of the crook, and here increases slightly in calibre until it reaches the maximum, which is at the crook, giving great strength to the female, where it is most needed, and places the extra metal within the bladder and prostatic portion of the urethra, where it is easily accommodated.

The shoe of the female blade is larger than the male blade, so that all débris is expelled and impaction of the instrument is prevented, and the wall of the bladder pro-

tected from being cut or pinched. The female blade is elliptical, giving thick septum, without increasing the calibre of the shaft. The female blade is made thin fore and aft, taking up less room in the bladder. The proximal surface of the female blade is in the form of a wedge of about forty five degrees, in order to penetrate the calculus with the least power of propelling force. The cross ridges on the proximal surface of the male blade prevent the stone flying when broken, and the parallel spillways permit the débris to escape without causing impaction of the instrument. The spur rises to a greater height on the male blade, to give it greater strength. This spur interferes in no way with the holding of the stone, if it does not touch it. The great breadth of the septum of the female blade is permitted by the elliptical shaft.

Handle or Screw Mechanism.—The handle or screw mechanism is of the interrupted screw type. It consists of the internal screw throughout the barrel having the threads cut away for the entire length of the barrel at alternate spaces of ninety degrees each.

The screw barrel has an end movement in the cylindrical barrel of about one-sixteenth inch. Working in this barrel is a pair of screw blocks with interrupted screw threads alternating spaces of ninety degeees each, so that they may slide up and down the barrel without engaging, but by turning the handle they engage immediately. One screw block is rigidly keyed to the screw handle shaft, and the other so formed that it has a motion of ninety degrees around the handle shaft. When turned to the right it locks or engages. When the calculus is crushed, the instrument may be unlocked simply by turning the handle to the left until it stops, which is never more than half a turn.

Owing to the one-sixteenth inch play of the screw barrel, the cylindrical handle readily adjusts itself to engage the threads of the screw block, and the calculus is, therefore, never dropped, in order to locate the instrument.

Slow Thread.—The screw thread is made slow to increase the crushing strength and for the important factor of time. A certain pressure may be applied to a stone without crushing it, which, if allowed to remain acting upon the stone for a short time, will crumble it without further pressure, and thus the instrument is not unduly strained. The screw handle is larger than the ordinary one. It is made of very thin sheet metal; strong and light as the lightest handle now employed.

The instrument has broken one hundred and fifty-eight calculi, of various shapes, sizes, and degrees of hardness in the testing machine, and been subjected to a pressure of five hundred pounds between the blades thirteen times. Its ultimate strength after this trying ordeal was six hundred and fifty pounds. Moreover, after this enormous pressure, the instrument was closed and could have been introduced and withdrawn from the living human bladder with ease, and without injury to the parts.

Extirpation of the Larynx.—Dr. W. H. Carmalt, of New Haven, read a paper with this title, dealing chiefly with the after effects. He operated with the idea of doing away with the opening into the mouth. Many had doubtless seen the case of a man whose larynx was taken out, who was afterward able to sing and speak; and this, without any communication between the mouth and lungs. The opening of the trachea being directly above the sternum. The man swallows a certain quantity of air and makes a little puffing around the trachea; holding this for a few moments he is enabled to speak. He is able to count up to twenty when he stops and refills his mouth with air. In the speaking case, it was determined to close the upper opening in extirpating the larynx.

History of the Case.—Two years ago the man complained of hoarseness. Examination revealed only a swelling of the right vocal cord. He passed out of observation until four months before the operation, when he again came under observation with a distinct swelling of the vocal cords and the parts above. He again passed out of observation until about two weeks before his admission to the hospital, when he was threatened with suffocation.

The attacks of dyspnœa, under local applications, became less until after five days, when he had an attack of dyspnœa one night that required tracheotomy to prevent death. His symptoms subsided, and we were able to wait and prepare for the necessary steps of the operation.

Operation.—The entire larynx was involved with a cancerous growth which extended to the trachea, which condition was not revealed by the laryngoscope.

The entire larynx, together with the first ring and upper half of the second and third rings of the trachea, were removed and the opening into the mouth closed. The epiglottis was not removed.

Result.—The day following the operation he was able to swallow his food.

The operation was performed on the 5th day of April, and his recovery has been uninterrupted. He is achieving a voice, though it is a poor one. He is able to whisper.

The principal object of this paper is to call attention to the fact that an artificial larynx is unnecessary.

Dr. Forbes called attention to the patient who had been operated upon in Philadelphia, and said the patient's ability of speaking was due to his ability of keeping the air in his throat, on the same principle as the Scotch bagpipe; and by practice he will improve in both length and quality of speech up to a certain point. He cannot vary his voice, such as elevate or depress it. The note is no more than the same as the bagpipe; a monotonous drone, but it is superior to an artificial larynx.

Dr. Hingston, of Canada, said one man had his tongue removed, and could speak; another had his jaw removed and could speak; and now here is a man without a larynx and also able to speak. He thought it difficult to say which was the principal organ of speech.

The President closed the session with a short farewell address, and the meeting adjourned until its next annual meeting, to be held in New York in the spring of 1895.

The following officers were elected for the ensuing year: *President*, Dr. F. S. Dennis, of New York; *Vice-Presidents*, Drs. D. J. R. Weist, of Richmond, Ind., and J. B. Roberts, of Philadelphia; *Secretary*, Dr. M. H. Richardson, of Boston; *Recorder*, Dr. DeForrest Willard, of Philadelphia; *Treasurer*, Dr. N. P. Dandridge, of Cincinnati.

AMERICAN PEDIATRIC SOCIETY.

Sixth Annual Meeting, held in Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from Vol. 45, p. 770.)

Third Day, Thursday, May 31st.

Dr. F. Forchheimer in the Chair.

The Nutritional Element in the Causation of Neuroses.—Dr. Christopher, of Chicago, read a paper with this title. He began his remarks on the triad of hereditary, anæmia, and local reflex causes, as given by Rachford. But as neuroses often occur in those not anæmic, *i.e.*, oligo-cythemic, the term malnutrition is preferable. The chemical composition of the nutritional supply may be at fault.

As a definition "a neurosis is a group of phenomena resulting from abnormal action or nutrition." It may be due to: 1, Chemically abnormal nutrition; 2, physically abnormal, as heat or cold; 3, a toxine; or 4, occur under improper trophic influences. Such tissue starvation may be due to deficient quantity of nutrition or a food incomplete in parts of its composition, *e.g.*, fat-starvation = rickets; starvation of salts = scorbutus.

Not all proteids are equally available in digestion, but milk gives several, all of which are readily convertible. Complete and incomplete starvation of tissue may coexist. Hence we have physiological starvation. We may

also have pathological starvation from syphilis, tubercle, etc.

The author counts the sweating of rickets a neurosis of fat-starvation. Under heredity he says, atavism, morphologically, is of no account, but chemically it gives rise to clashing of functions resulting in lithæmia, for example. Neuroses are due to perverted action, but as this may occur in various tissues, the term "histoses" is suggested.

Dr. Rotch endorsed the conclusions regarding fat-starvation and said that he was making careful analyses of the salts of milk, which he hoped would prove of much value in our understanding the management of rickets and scorbutus.

A Case of Cyanosis.—Dr. William P. Northrup, of New York, exhibited the heart of a case of congenital cyanosis, which lived to four and a half years notwithstanding severe attacks of measles and pertussis. The heart showed a narrow pulmonary artery, an opening between the right ventricle and auricle, and hypertrophy of the right ventricle. The cornus arteriosus was obliterated, the foramen ovale closed. As symptoms the child had the typical sluggish peripheral circulation, clubbed fingers, constant dyspnœa, and a purring thrill over the base of the heart with a systolic murmur in the left third interspace. The trouble appeared due to early fœtal endocarditis.

The question for discussion was whether cyanosis, a symptom, should continue as a name for a disease. Most of those present seemed to favor calling such cases malformation of the heart, abandoning the term "cyanosis."

Nomenclature of Diseases of the Mouth and of the Gastro-enteric Tract.—The committee on revision of this subject presented its report through the chairman.

The report was adopted, and will appear in full later in the *Archives of Pediatrics*. The idea in the revised nomenclature is to eradicate old and useless names, and to adopt a nomenclature such as will enable men in different parts of the world to understand what each is writing about.

Election of Officers.—The following officers were elected: *President*, Dr. F. Forchheimer, of Cincinnati, O.; *First Vice-President*, Dr. Lewis Starr, of Philadelphia, Pa.; *Second Vice President*, Dr. August Seibert, of New York City; *Secretary*, Dr. Samuel S. Adams, of Washington, D. C.; *Treasurer*, Dr. C. W. Townsend, of Boston, Mass.; *Recorder*, Dr. Dillon Brown, of New York City; *Member of Council*, Dr. B. K. Rachford.

The Early Diagnosis of Pott's Disease.—Dr. Dillon Brown, of New York, then presented a long and thorough study of "The Early Diagnosis of Pott's Disease of the Spine in Children." The author went carefully into the differential points between this disease and others simulating it, or remotely connected therewith. He cited many cases in which the patients had been treated for dyspepsia, peritonitis, cold abscesses, rheumatism, paralysis, etc., the real lesion remaining long unrecognized or being only found upon autopsy.

On the other side, cases were recorded having a diagnosis of spinal caries, which proved to be sarcoma of bone, a glioma of cervical medulla, and the like. As nearly all these cases were reported by men of large experience, it shows the necessity of great care and exactness in diagnosis as well as treatment. The disease is now recognized as a chronic tubercular lesion of the vertebra, and as ninety per cent. of cases occur in childhood, we must be on our guard. The presence of syphilis or traumatism as a cause must be sought for. Rheumatism is to be excluded by treatment if the symptoms are uncertain.

Fourth Day, Friday, June 1st.

Infantile Myxœdema.—Dr. William P. Northrup, of New York, read the paper, which was a preliminary report of two cases being treated by thyroid extract. In future further account will be given of their progress. The first, a girl, nine years of age, was of good family history, the parents non consanguineous. She had lived in Ohio and Pennsylvania. She had grown none since nine months of age, and had but fourteen deciduous teeth. She presented the usual characteristics of cretins, puffy look, parchment like skin, flat nose, swollen tongue, protuberant belly, and umbilical hernia. She could say only one word, but was of lively disposition. This child was treated for eighty days with glycerine extract of sheep's thyroid. The dose, one minim, three times a day, increasing a minim a day until the temperature remained at 100° F. At the end of eighty days the child was much improved, taking more food, and having a brighter countenance.

The second case was twelve years of age. The same treatment was employed, but the results were less marked.

Successful Treatment of Infantile Myxœdema.—Dr. Osler, of Baltimore, then read a paper with this title.

Case I. was a boy, aged four years and eight months, who took one quarter of the thyroid gland of a sheep each twenty-four hours. After a time this was administered desiccated. In fourteen months the boy grew four inches, an unusual increase. He now walks and runs about, and has gained so much mentally that few would think him "queer." The myxœdematous appearance is all gone.

Case II. was a male, aged nineteen, who made no material gain, partly because treatment was omitted for three months.

The third case was lost track of.

In discussion Dr. Carr referred to Dr. Crary's case, which is growing rapidly and gaining mentally.

Dr. Forchheimer related three cases under his observation. In the first patient, a boy, aged nineteen, the thyroid extract had to be discontinued because of the maniacal excitement it produced. A second case, aged eleven months, is improving on the extract. In Case III., aged four years, there is no change. The treatment gives promise of benefit, therefore, but is not a certain cure.

Acute Pyelitis in Infants.—Dr. L. Emmet Holt, of New York, read a clinical paper on the above topic. Acute pyelitis may follow any other acute disease. Case I. was a child, eight months old, nursed. It suddenly had a temperature of 103.5° without any discovered local cause, pneumonia was suspected. The urine was collected in a two ounce conical glass and showed three quarters of an inch of pus and a trace of albumin; there were no casts, nor was any treatment instituted. The child is now well.

Case II. was a female child, aged eight months, who had been nine days ill. The temperature ranged from 103° to 106° F. Symptoms all negative but pneumonia suspected as before. On the eleventh day the urine showed pus and albumin with bladder epithelium, but no casts. There was no dropsy. Two days later the urine contained eight per cent. of pus. The child took twenty grains of citrate of potash daily, and in three weeks all pus had disappeared.

Case III. was aged nine months; previously never ill. The child had repeated chills in one day and a temperature reaching 104° F. in the rectum. Between chills the temperature would fall to normal and all appear well. Two grain doses of quinine were given every three hours. On the fourth day the child took fourteen grains of quinine. Little urine was passed, and that with pain. It contained one-fifth pus and a little albumin; specific gravity, 1.012. On the sixth day sixteen ounces of urine was passed without irritation of the bladder. However, the child took but half its usual amount of food. The irregular fluctuations of temperature continued and a few granular casts were found in the urine. Although the spleen was at no time enlarged, Dr. Ripley, the consultant, advised more quinine hypodermically. Eighty grains were thus administered in seventy-two hours without bad effect. The chills and fluctuation of tem-

perature were stopped. Lithia water and hot fomentations were used as treatment. The urine now was alkaline in reaction, sp. gr., 1.007, contains albumin, 3.6 grains of urea per day, a few red and many white blood-cells, with bladder epithelium.

In review the author noted that the first case was mild and recovered without treatment. The second case had a temperature about 105° F. for twelve days, not affected by quinine. Though the temperature was higher there was little prostration. This case occurred during the influenza epidemic, and had no suspicion of malaria about it. The etiology of Case III. is doubtful; was it septic or malarial?

Dr. Osler mentioned a case, three years of age, who had recurring chills several months. After each chill the urine would be turbid, acid, and full of pus. Although the spleen was not enlarged, the boy had been saturated with quinine. Treatment was thought of no further avail, but the boy having a phimosis, the father wished that remedied. There was no return of the attacks after the circumcision. The speaker believes that malaria may be excluded without a blood examination. It is a rule that a fever that resists quinine is not due to malaria.

Dr. Seibert suggested vulvo vaginal catarrh extending into the bladder or farther and causing suppuration.

Dr. Holt, in closing, said it had been his fortune to see a number of cases of purulent infiltration of the kidneys, all of whom died. Such cases were quite distinct from pus in the pelvis of the kidney. The absence of mucus and of alkalinity assures the case not being cystitis.

Giant Fingers.—Dr. F. Huber, of New York, exhibited a plaster cast and photograph of such a case. The most enlargement and distortion was of the second finger.

Medical Septicæmia in Children was the subject of an address by Dr. W. S. Christopher of Chicago. He spoke in part as follows: We all see many cases of fever which do not fit the description of typhoid, malaria, influenza, or scarlatina. This term is not a scapegoat, but a term under which these endemic fevers may be classed until we can properly differentiate them one from another. Medical septicæmia indicates that it is non-traumatic. The case was then cited of a child, aged twenty months, who had a diarrhœa of three weeks. The temperature was 105° F. but erratic. Scarlatina was ruled out in a few days, typhoid fever also Two days later it seemed surely to be peritonitis. The peritoneal cavity was then irrigated with a sterile normal salt solution. The following day pneumonia developed, but all was recovered from. Here it is fair to infer that the same micro organism caused the inflammation of bowel, peritoneum, and lung, whether appendicitis or no matters not.

In a recent epidemic of twelve such cases three had laryngisums stridulus, followed by fever for two weeks and indigestion. Eight similar cases occurred which must be grouped, and medical septicæmia is a generic name that suits. Some forms of dysentery would belong here, but not the amœbic dysentery.

Dr. Caillé said he should think it difficult to distinguish between a medical and a surgical septicæmia. True, it might be often hard to locate the source of infection, but having located it treat accordingly.

Dr. Fruitnight thought such a nomenclature should be deferred until the cases are differentiated.

Dr. Holt believed that many such fulminant cases would upon autopsy prove to be pneumonia.

Dr. Adams considered the term evasive rather than helpful, and thinks most such cases as described are atypical typhoid.

Dr. Christopher, in closing, declared that an anatomical diagnosis is useless, for we cannot know always without autopsy. He therefore felt that there was need of the class medical septicæmia.

Mirror Writing.—Dr. George N. Acker, of Washington, exhibited a negro boy, aged ten, who is naturally a mirror writer. He writes equally well with either hand, the left beginning on the right side of the paper with the letters slanting to the left. In playing marbles the boy's left hand is the surest. The patient's personal history and heredity were negative. His mind is quick and he is rather cunning.

Before closing Dr. Forchheimer made a few remarks thanking the Society for the honor they conferred in electing him President for the coming year, and with best wishes "auf wiedersehen" adjourned the meeting to next year at Hot Springs, Va.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Eighteenth Annual Meeting, held in Washington, May 29, 30, 31, and June 1, 1894.

(Continued from Vol. 45, page 764.)

Second Day, Wednesday, May 30th.

Adeno-carcinoma of the Skin Starting in the Sweat-glands.—Dr. Fordyce, of New York, exhibited microscopic specimens and photographs showing the structure of the malignant growth. He stated that, although a number of pathologists had claimed a sweat-gland origin for certain clinical varieties of skin cancer, only a few cases were on record in which such a point of departure had been proven. In the case in question, the new-growth is a proliferation of the columnar cells lining the sweat-glands, which broke through the membrana propria and infected the surrounding connective tissue. The tumor was removed from the leg of a man, thirty-five years old, and was about two-thirds the size of an egg.

Dr. Fordyce also demonstrated the intra-cellular bodies which are looked upon by many as the cause of cancer. He expressed himself as a believer in the parasitic nature of cancer, but was not prepared to admit that its etiology had yet been made clear.

Dr. Hartzell said that the essential characters of the cells were not changed. He believes the disease to be of parasitic origin, and that the growth of the cells was more rapid when the parasites were in greater number.

Dr. Bronson asked whether the origin in the sweat-glands had any effect upon the induration of the lesion.

Dr. Fordyce replied that he had found such epitheliomas to be quite soft.

Contagiousness of Molluscum Contagiosum.—Dr. Stelwagen, of Philadelphia, read a paper on this question. He quoted a large number of clinical examples of the communicability in households and in institutions. Among others, that of a nurse who had received the disease from a child, who had received it from another nurse. The latter had given the disease to other children. He quoted an example where there were three cases in one family who had infected a young friend who played with them. Also the case where there was an eruption in a man and his wife about the genitals. A case where a brother and sister used the same towel and were both infected. He gave a very exhaustive *résumé* of the reported cases of the contagiousness of the disease. In an epidemic in a hospital for children, two weeks after the first case was observed, there were forty-one cases in the hospital. The long period of inoculation is remarkable. He doubts whether the psorosperm is the cause of the disease.

Dr. Fordyce believed the disease due to an animal parasite, probably the psorosperm.

Dr. Hartzell believed in the etiological relation of psorosperms and this disease.

Dr. White thought that there had been no demonstration that the bodies found in the cells were parasitic and introduced from the outside.

Ichthyosis Congenita (so-called Harlequin Fœtus).—Dr. Sherwell, of Brooklyn, reported a case of universal ichthyosis in an infant. The parents were absolutely healthy and had two other children, both healthy. The child was born at term and weighed two pounds. The whole surface of body was covered with soft, horn-like

scales. The scales on the head were more sebaceous. The flexures were deeply fissured. The mucous surfaces were only slightly affected. There was slight ectropion. Alkaline baths and inunctions of vaseline and ung. aq. rosæ were employed in the treatment. When bathing and inunctions are neglected, extensive scales form on body. The child has been much improved by the treatment.

Protozoa-like Bodies of Herpes Zoster; a Contribution to the Study of Psorothermosis.—Dr. M. B. Hartzell read a paper on this subject, in which he called attention to the bodies resembling protozoa in zoster, varicella, and variola. Pfeiffer was the first to describe them as protozoa, and thought they gained access by the intercostal vessels. There were three varieties. These bodies have a cell body proper, an internal capsule, and a cavity containing several small oval bodies. The second variety is much larger than the first. The body of cell stains feebly. The internal capsule stains deeply. Some of the bodies are found free and show amœboid movements. He found in a case of recurrent zoster the same alterations as in ordinary zoster. He thinks we have a metamorphosis and increased vital activity of the epithelial cells.

Third Day, Thursday, May 31st.

Angioma Serpiginosum.—Dr. J. C. White, of Boston, read a paper entitled "Angioma Serpiginosum and Some Other Dermatoses."

In the case of angioma serpiginosum, from the border of right scapula to nipple there were twenty-four lesions of pin-head size and of a red color. They disappeared partially under long pressure. These lesions increase in size and finally undergo evolution in the centre, the border forming circles or segments of circles. The skin in the centre appears normal except the red color. New foci appear and follow the same course. The disease spreads in an annular manner for an indefinite period, and appears as pale scar-tissue surrounded by scarlet rings.

The writer said that small aggregations of cells are found in the corium in this disease, which are unlike the round granulation cells. Small places in vessels were found filled up with small granular masses, resembling amœboid forms of lower organisms. There seemed a fusion of degenerated cells in the nodules which appeared to undergo degeneration by the strangulation of the blood-vessels. The pathological anatomy of this disease has a great resemblance to that of the pigmented moles.

Acquired Idiosyncrasy for Quinine Showing Peculiar Cutaneous Manifestations.—Dr. Charles W. Allen, of New York, read a paper with this title. He said that the most frequent eruption caused by this drug is an erythematous rash beginning on the face and extending over the whole surface. Other usual forms are the urticarial and papular, while the vesicular, bullous, and purpuric are less frequently seen.

In the case reported by Dr. Allen the subject had previously been able to take quinine in moderately large doses without ill effects. The peculiarities of the case reported are: 1. That the eruption is developed by a very small quantity of the drug; 2. That the lesions are local and show no tendency to spread; 3. That the location of the individual spots is always the same. 4. That the eruption was produced four times accidentally and fourteen times experimentally. The writer says that the simple erythema of one attack may in another attack closely simulate an erythema exudativum multiforme. The patient, in the case reported, took a five-grain dose of the sulphate of quinine at bedtime. During the night a general pruritus developed, and in the morning large erythematous blotches were found on certain parts of the body—on the next morning the prepuce presented large excoriated surfaces suggestive of chancroids. The rest of the glans and prepuce was red and sensitive. The quinine was discontinued, and in about a week the spots desquamated and faded in color. Some months later the patient having taken one "Monsette" pill, not knowing that it contained quinine (about one grain) developed within twelve hours itching, burning, and prickling sensations, and the same spots appeared as before. The whole prepuce was again excoriated. He developed the same symptoms in the same year after taking a cordial glass of coca wine, although in a less pronounced way. The quantity of the drug was exceedingly small.

In this patient, a few hours after taking about one-third of a grain of quinine, the glans penis was surrounded by a ring of redness and the same spots as before developed on the body. Dr. Allen experimented with various salts of quinine, such as the hydrobromate, the hydrochlorate, the bisulphate, dextro quinine, and the bimuriate with urea. The same manifestations invariably followed. These investigations prove that the statement which has been made, that the acid and not the case is the offending substance, is incorrect.

The writer proved by experiments upon this case that the theory of reflex dilatations of the vessels of the skin from stimulation of the sensory nerves of the stomach was not applicable. General symptoms followed holding one-fourth grain of the carbamide in the mouth for fifteen minutes. Quinine given in a suppository and by inunction produced a distinct erythema. A weak solution of quinine in alcohol rubbed into the scalp caused the same symptoms. Dr. Allen noticed in this patient a marked tenderness on pressure over the spinous process of the second dorsal vertebra. Upon this symptom he bases his supposition that the eruption is due to an angio paralysis of central spinal origin. He believes the symmetrical distribution and circumscribed features of the eruption are explained by the theory of nerve origin, as in large doses the reflex function of the cord is lessened and ultimately abolished. The writer thinks it rational to refer these skin changes to an action upon the cord.

Symmetrical Cutaneous Atrophy of the Extremities.—Dr. Bronson, of New York, reported the case, which was a very rare one, only four of the same variety having been found in the literature. Buchwald, of Breslau, was the first to describe this form, and so peculiar were the manifestations of the disease, and so well delineated were they, that the term Buchwald's atrophy was suggested. The affection, which is clearly an idiopathic form, differs from the ordinary atrophia cutis propria in its symmetry and in its tendency to gradual progression and in the fact that the atrophy seems to be of a qualitative kind as well as simply quantitative or degenerative.

The case described by Dr. Bronson affected a patient forty-five years of age, who was a working-man of fairly good family and personal history, and who, except for the atrophic disease, appeared to be in possession of perfect health. The disease had begun about fourteen years ago, and latterly had remained nearly stationary, at least so far as the extent of the disease was concerned. It occupied the entire surface of both lower extremities from the upper part of the feet to Poupart's ligament in front, and extended over the nates behind, leaving the cleft of the nates, however, as well as the genitals, free. The arms were similarly affected from the base of the fingers behind, and from the wrists in front to about the junctions of the lower with the middle third of the upper arms.

The chief marks of the atrophy were the thinning of the skin, discoloration, wrinkling of the surface, and a multitude of shallow depressions scattered over the surface. The skin was everywhere freely movable, and could be lifted in thin folds from the subjacent structures, which folds subsided again to the general level slowly when released, as though the skin had lost elasticity. Everywhere were numberless fine wrinkles which followed the cleavage lines of the skin—they enclosed smooth, shiny interspaces, and gave the appearance of a crumpled piece of gold-beater's-skin. The wrinkling was most marked about the joints, especially the knees,

backs of wrists, and the nates. The discoloration was due in part to brownish pigmentation, that was in most parts punctate, in part to the purple color of the veins, which showed through the thinned and abnormally transparent epidermis with uncommon distinctness, and partly to a red reflex from the arterioles. In a recumbent posture the color of the legs and thighs was more brown, but after standing awhile the veins became turgid with blood, and the surface appeared cyanotic. There was no impairment of sensation in the affected parts, but rather hyperæsthesia. The hairs had nearly disappeared, as also the perspiratory function.

Relation of Impetigo Herpetiformis and Pemphigus Vegetans —Dr. Joseph Zeisler, of Chicago, presented a communication with this title, in which he said that to anyone who has carefully studied the literature and the descriptions of impetigo herpetiformis and of pemphigus vegetans, respectively, it must have become apparent that while each of these rare disorders seems fairly well established as clinical entities, they have many features in common, which occasionally make their differentiation exceedingly difficult even for the expert dermatologist. The speaker referred to the writings of Duhring, Dumesnil and Marx, and of Dubreuilh, who had commented upon a case of impetigo herpetiformis (published by himself in 1887) in a way which shows that while some of them accept his case as a typical instance of that disease, others considered it as an example of pemphigus vegetans. The points of similarity of the two diseases are there more fully detailed. The prevalence in women, the inception on some mucous membrane, the peripheral extension of the cutaneous lesions, the localization on certain places of predilection, the occurrence of vegetations on places where moisture, warmth, and friction exert an influence, the fatal termination, the obscurity of the etiology and pathology are referred to more particularly. The differentiation in a doubtful case will have to be made according to the principle *de potiore denominatio fiat, i e.*, where miliary pustules form the chief lesions during most of the time, impetigo herpetiformis will be declared, while, if bullous lesions predominate, pemphigus will be the diagnosis. The writer thinks the criticisms of various writers concerning the description of such rare cases are unjust, for the reason that variations from the well-established type of any disease are always liable to occur.

Dr. Bronson showed a combined comedo expressor and dermal curette of his invention.

Dr. Gilchrist, of Baltimore, showed some microscopical preparations containing protozoa.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twentieth Annual Meeting, held in Washington, D. C., May 30 and 31, and June 1, 1894.

(Continued from Vol. 45, page 772.)

Second Day, Thursday, May 31st.

A New Neuroglia Stain —Dr. W. J. Morton, of New York, presented some microscopic slides showing the new neuroglia stain of Weigert, presented to him by Dr. Weigert on a recent visit to his laboratory in Frankfort. The neuroglia fibres are stained blue, while the nerve elements are either not stained at all or at least very faintly. The medullary sheaths do not accept the stain, and thus the field is left clear for the differentiation of the neuroglia fibres. Dr. Weigert is not yet quite ready to publish this new stain, although he has been at work upon it for five years; no specimens have hitherto been exhibited on this side of the Atlantic.

Multiple Neuromata.—Dr. Morton also read a paper entitled "A Case of Multiple Neuromata, with Exhibition of Microscopic Sections of a Large Neuroma Removed from the Ulnar Nerve." The tumor developed upon the ulnar about half way between the elbow and the wrist, and was about the size of a hen's egg. Cutting down upon the mass with a view of severing and suturing the nerve if necessary, or of dissecting out so far as possible its strands, he found that the tumor was lying quite free, except for a few thread like adhesions, within a capsule, and that the nerve traversed this capsule from end to end, in five separated bundles. It was therefore possible to enucleate the tumor and replace the nerve strands without the slightest injury to the latter.

The tumor was a myxo-fibroma. The encapsulation of the tumor, and at the same time the confinement of the nerve bundles to the capsule, was novel and of importance to bear in mind in further operations upon such growths.

Crossed Knee-jerk.—Dr. Guy Hinsdale and Dr. J. Madison Taylor, of Philadelphia, presented a communication with this title. It was based on studies of over one thousand cases of nervous disease observed at the Infirmary for Nervous Diseases, Philadelphia, and the institutions for feeble-minded at Carlisle, Pa., and Vineland, N. J. In using the term crossed knee-jerk, it is meant that, the patella tendon being struck, the opposite leg is instantly made to approach its fellow; hence the phrase "in knee jerk," or "contra-lateral knee-jerk," may be used to describe this action. The movement observed in the limb opposite to that in which the patella tendon is struck is not an extension of the leg so much as an adduction of the thigh (vastus internus and crureus). The best attitude for eliciting the movement is not that which permits the freest knee-jerk, such as sitting on the edge of a table. It demands rather more ease of lateral motion of the thigh. This is accomplished very well by seating the subject at ease in a chair with the body erect and the knees ten or twelve inches apart, with the knee joint at rather an obtuse angle, the feet being advanced a few inches.

The phenomenon is observed in a small proportion of normal persons, and in from twenty to thirty per cent. of the cases coming to a clinic for nervous disease. It is observed in a large majority of spastic cases. It is distinctly proved not to be due to a communicated shock or jar to the pelvis, by reason of its absence in all cases of locomotor ataxia, and its production in favorable cases on suspending the subject from the floor and observing the adduction of the thigh on tapping the patella tendon or, as in one case observed, tapping the tendo Achillis.

Crossed knee jerk is also found to be reinforceable. Tracings were shown which recorded, in a normal subject, an adduction in crossed knee jerk of one-sixteenth of an inch, in a spastic one fourth of an inch, and in the latter case, under reinforcement, half an inch. Reinforcement produces the movement in some cases where it is not otherwise evident. A case was related in which a very slight tap on the patella tendon causes violent contractions of both legs, causing the knees to smite together, or cross over; a larger tap will cause, in addition, crossing of both arms in a sort of lock spasm, requiring aid afterward in stretching out the limbs.

The reflex arc involved in movements of this kind is held to embrace the cerebrum.

Dr. H. R. Stedman, of Boston, asked if this condition was not somewhat similar to the so-called allocheiria.

Dr. Walton thought that a practical result, bearing on diagnosis, could not fail to follow careful and systematic investigations of these anomalous reflexes. We have not exhausted the directions in which the reflex impulses may be deflected. He had found not only the classical reflex, described recently by Remak, of toe flexion on stroking the inside of the thigh, but had seen both dorsal and plantar flexion of toes on stroking various areas in the lower extremities in case of broken back.

Dr. Morton spoke of the application of faradism to the right sciatic nerve as having produced a reaction in the muscles of the left shoulder.

Dr. George Jacoby referred to a paper read by him a few years ago in which he had called attention to the phenomenon of irradiation of the electrical current.

Dr. Mills believed that the best explanation would be forthcoming from a careful study of the distribution

of cells and fibres in the cord and their relation to other parts of the system.

The President considered the title of the paper an unfortunate one, and did not look upon this phenomenon as a crossed knee-jerk at all, but as a contralateral muscular contraction. He thought its reflex character was quite doubtful and that there was no difficulty in accounting for irradiation on anatomical grounds.

Dr. Dercum, of Philadelphia, exhibited a skull which had been kindly loaned by Mr. Bailey Willis of the Geological Museum. It belonged to the Peruvian Government, and its origin was traced to pre-historic times. It was shown as an illustration of the ancient method of trephining.

Recurrent Oculo-Motor Paralysis.—Dr. Knapp, of Boston, read a paper with this title. A man of forty-one, with some nervous heredity, had had severe neuralgic pain over the left eye, with ptosis, external strabismus, and numbness of the face, a year before he came under observation. This lasted seven weeks. In December, 1892, one year later, he had intense pain in the left side of the head, with nausea and vomiting. There was complete paralysis of the left third nerve, with anæsthesia of the nose and cheek on the left side, and paræsthesia of the forehead. Photophobia was present. The anæsthetic region was extremely tender on pressure, and there was increased discharge from the left nostril. After two months the paralysis began to diminish, and after four months it had almost wholly disappeared; but the sensory symptoms still continued in a lesser degree. Statistics were given of forty cases, and of ten other cases of a doubtful nature. In only six cases has there been complete recovery from the paralysis in the interval between the attacks, and in four more the pupil remained dilated. In seven cases there was at first complete recovery, but in the later intervals there was some paresis. Senator's division into periodical and periodically exacerbating cases hardly seemed warranted, and, although some of the cases resemble migraine, the affectiou in most cases is not at all like migraine. Three autopsies have shown lesions involving the nerve, and most cases are probably due to such lesions.

Dr. Mills had observed several cases of recurrent ocular palsy with involvement of the fifth nerve. He had also seen cases of recurrent facial paralysis. The only probable explanation in most cases is that of organic lesion. He thought Knapp's cases were probably due to lesion of root fibres.

Dr. Morton Prince agreed with Dr. Knapp in believing that these cases were caused by organic lesion. He believed that pain as a localizing symptom possessed very little value. He would rather depend upon motor and sensory paralysis.

Dr. Walton thought all cases could not be classed together. While many were of nuclear or vasal origin, possibly some of the less grave cases were due to recurring œdema or possibly vascular disturbance at the cortex, which would perhaps explain the coincidence of motor and sensory disturbance. Possibly some cases were allied to the severer form of hysteria.

Dr. Knapp, in closing the discussion, said that there was no case of complete recovery on record where there had been both motor and sensory involvement. In cases of syphilitic origin where only one or two branches were involved, it was more likely to affect the nerve after it had left the pons.

Circumscribed Softening of the Pons, Internal Capsule, Caudatum and Lenticula.— Drs. Charles K. Mills and John Zimmer, of Philadelphia, reported a case which presented two limited lesions of unusual interest—one in the pons, and a second involving the internal capsule, and a small segment of the caudatum and lenticula. The patient, a woman, aged forty-two, had a previous history of alcoholism and of acute articular rheumatism. Examination showed slight impairment of mental action, marked somnolency, and imperfect articulation. At rest, the right eye turned strongly to the right, while the left was not deviated. Both eyes could not be turned together to the left. The lateral movement of the left eye to the right was also impaired, and slight nystagmus of both eyes was present. The lids of the left eye could not be brought fully together. Right facial paresis was present, but the tongue was not deflected. Tendon and muscle phenomena were much exaggerated in the paretic limbs. Anæsthesia could not be discovered in any portion of the body. About eleven days after admission, she had a second apoplectiform attack. She was now totally unable to articulate, but understood what was said. She was also unable to expectorate, and there was interference with swallowing. A thorough and careful autopsy made by Dr. Guiteras revealed a circumscribed softening of the pons. The lesion, at its cephalic extremity reached to within 1.5 mm. of the ventral surface of the pons—laterally extending to the raphe, and about the middle of the pons slightly across the mesial line. The area of softening became smaller and more deeply situated as it approached the post-oblongata, which it almost but not quite reached. The second lesion was revealed by a vertical transection of the right basal ganglia and capsule. The widest portion of the lesion corresponded to the plane of the cephalic extremity of the thalamus. It was about 17 mm. in its antero-posterior extent. The pontile lesion probably involved the root fibres of the abducens, and the fibres connecting it with the facial fibres or nucleus. The position of the lesion was such as not by any possibility to involve the cell-nests of these nerves. The lesion involved the crustal portion of the pons, including a portion of the pyramidal tracts, and the deep transverse fibres. The lesion of the internal capsule was beautifully localized near the genu, probably involving the geniculate and speech tracts.

Lesion of Thalamus; Death from Intestinal Hemorrhage.—Dr. Wharton Sinkler, of Philadelphia, read this paper. He referred to the importance of placing on record all facts relating to the function of the thalamus, and stated that his attention had been drawn, in connection with the case which he reported, to the observations of Lussana, Brown-Séquard, Ebstein, and Schiff, many years ago, in which they produced ecchymoses and hemorrhages into the mucous membrane of the stomach and colon of some of the lower animals, by wounding the corpora quadrigemina and optic thalamus.

The patient was a man aged sixty-seven, who had worked for many years in a stone quarry, and had received frequent slight injuries to the scalp, in consequence of being struck by fragments of stone. In July, 1892, after having been exposed to the sun, he was suddenly taken ill and had to be removed to his home in an unconscious condition, where he was seized with convulsions, which lasted for the greater part of two days. After a month he was able to resume his work; but two weeks later he began to have epileptiform convulsions, which recurred at irregular intervals of from one to two a week. The seizures were always preceded by an olfactory aura, the patient observing the smell of burning sulphur. After a few months the patient had maniacal attacks after his fits, and was removed to the Philadelphia Hospital in December, 1893.

There was nothing notable about his condition, except that the attacks of epilepsy were of the precursive form. He would run violently, and imagined that he was pursued by devils. Toward the end of February he had an attack in which there was rise of temperature without any physical reason being discoverable. His intellectual powers failed; and he gradually fell into a somnolent condition, which lasted for nearly three weeks, at the end of which time he was suddenly, without premonitory signs, seized with intestinal hemorrhage of a profuse character, from which he died in about twelve hours.

At the autopsy the mucous membrane of the colon was found to be softened and deeply injected, but no lesion was found in the way of an ulceration, or rupture of a vessel which would account for the hemorrhage. The brain showed very marked evidence of an old lepto-men-

ingitis over the left hemisphere, and there was atheroma of the vessels of the base. In the posterior right thalamus there was found a small area of softening. It was about one-third of an inch in length, by one-fourth of an inch in its transverse diameter. No other coarse lesion could be found in the brain.

Cerebral Hemorrhage: Its Causes and Premonitory Symptoms.—Dr. C. L. Dana, of New York, presented this paper, based upon the study of 100 consecutive cases of apoplexy with hemiplegia, observed at his clinic at the Post-Graduate Hospital, and 79 cases of apoplexy, with autopsy, observed in Bellevue Hospital; 30 of the latter came under his personal care and observation. Of 100 non-fatal cases 36 were due to syphilis. The special characteristics of the attacks due to syphilis are that they occur in early life; they are often multiple in character, and the pathological condition underlying them is usually a thrombosis and softening. So far as his experience and records went cerebral hemorrhages are rarely repeated, and it seemed as if in many cases the rupture of an artery changed the vital conditions, as it certainly does the personal habits, so that the attack exercises a conservative influence upon the individual and actually tended to prolong life.

Dr. E. D. Fisher, of New York, presented a report of 77 cases. Fifty one had one attack; 16, two attacks; 9 had three, and 1 had six attacks. All are still living. These cases were observed in his service at the city almshouse. The average age at which the first attack occurred was $44\frac{6}{17}$ years. His observations, he thought, confirmed what had been said by the reader of the paper. The longest duration since the attack was twenty-two years.

Dr. Gray, of New York, thought that the fatal defect in the paper was that many things were confounded. It told us nothing as to the frequency of apoplexy, but left us in doubt as to the elements of diagnosis.

Dr. L. Weber, of New York, said that while he believed Dr. Dana's deductions from his own cases were of value, those from other sources did not seem to him to be applicable.

Dr. William A. Hammond doubted whether life was in any way protected by an attack of apoplexy, as the same causes would persist.

Dr. Wharton Sinkler had observed a case in which the attack occurred twenty-five years ago. The man did not seem to be in any way benefited in his general condition.

Dr. Prince thought the fallacy lay in the statistics as to those still living, as one cannot say how many attacks they are going to have.

Dr. Dana, in closing, said it was hardly fair to criticise his data, as sufficient time was not permitted for the reading of his entire paper.

Lumbar Puncture for the Removal of Cerebro-Spinal Fluid.—Dr. William Browning, of Brooklyn, N. Y., read a paper with this title. He reviewed the main points in this recently devised operation. Brief notes of a few cases were given as well as directions for its performance. The following conclusions were reached:

1. The method is simple, easily practised and rather attractive.
2. In itself it is usually without danger.
3. By it we certainly can draw off cerebro-spinal fluid.
4. The quantity removed at short sittings has been from one to one and a half ounce in adults.
5. This without doubt represents the amount of free fluid usually present in the lower vertebral canal even when occluded above.
6. In internal hydrocephalus the relief, if any, is but very temporary. In the common form due to tubercular meningitis the result is not worth the trouble; while in the closed or sacculated forms it must rather do harm than good.
7. As a diagnostic means, *e.g.*, in suspected meningeal hemorrhage, it is valuable. As an index of pressure it may also be worth noting.
8. It is worth further trial:—(*a*) As a passing relief in brain tumors not complicated by hydrocephalus; (*b*) As a substitute for trephining in progressive dementia; (*c*) In certain spinal troubles; (*d*) And possibly as a means of applying medication directly to the spinal meninges.
9. In conclusion it may be said that, while admissible in all cases of brain-pressure, there is as yet no established indication for this procedure except for diagnostic purposes.

Dr. Mills said that all operations of this kind are unphilosophic, and would accomplish nothing, as the fluid reaccumulates The same may be said of hydrocephalus. Some good may be done when the fluid is either blood or pus; otherwise it is not indicated.

Dr. Dana had utilized this method in three cases of alcoholic meningitis (in the so called wet-brain). Two recovered and one died. In the adult the operation is difficult. He agreed with Dr. Mills as to its indications and utility. He believed that the operation possessed, at least, some rational foundation.

Non-Operative Treatment of Brain Tumors.—Dr. Theodore Diller, of Pittsburg, was the author of this paper. The writer took the view that not all brain tumors which could be localized should be operated on. He cautioned against regarding as successes those which merely succeeded surgically. The obstacles in the way of a complete success were many, and the results were disappointing, in spite of the rich and growing knowledge of localization. Operations should not be undertaken unless the patient was getting worse in spite of medical treatment.

Dr. Starr spoke of the case of a man with a doubtful history of syphilis and all the symptoms of cerebral tumor. Its localization was a simple matter. Mercury was used and iodide of potash was given in doses of three hundred grains daily. There was marked improvement in all symptoms; and it seemed to be a case cured without operation. The patient died suddenly, and at the autopsy a cysto-sarcoma was found without any evidence of gummatous infiltration.

Dr. Putnam believed we should only operate when there were definite indications.

Dr. Sinkler mentioned the case of a man with Jacksonian epilepsy and no history of syphilis. Two years later all symptoms of tumor were present. Mercury and iodide were used, but he became progressively worse. An operation was performed but no tumor could be discovered. The wound healed well. Since then, the patient has improved steadily in all symptoms.

Dr Jacoby said that there was a class of cases presenting all of the symptoms of tumor which get well without operation. He cited the case of a man with many of the symptoms excepting optic neuritis, where he was unwilling to make a positive diagnosis. The plasmodium malariæ was found in his blood and he made a complete recovery under large doses of quinine.

The President stated that we have all been disappointed more or less in the results after operation. It may be our own fault on account of the delay in operating. He had a similar experience to that of Dr. Starr. At the autopsy there was found a typical glioma. The symptoms had entirely disappeared for several months. In another case with all the symptoms of tumor iodide had been used, but all symptoms subsided after thorough mercurial inunction.

An Electrode for Use in Diagnosis.—Dr. W. M. Leszynsky, of New York, presented an electrode which had been specially constructed with a view to its usefulness in diagnosis.

Stolen Grafts.—A man has brought suit in San Francisco for $25,000 damages, for the loss of some strips of skin removed from his thigh and grafted upon the head of another patient in the hospital. He claims that the grafts were taken without his consent and knowledge, while he was under the influence of an anæsthetic, given, as he was led to believe, to save him from the pain of an examination that was to be made by the surgeons.

ASSOCIATION OF AMERICAN PHYSICIANS.

Ninth Annual Meeting, held in Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from Vol. 45, page 802.)

FOURTH DAY, FRIDAY, JUNE 1, 1894.

The Chemical Products of the Anaërobic Putrefaction of Pancreatic and Hepatic Tissues, and Their Effects upon the Tests for Morphine.—DR. VICTOR C. VAUGHAN, of Ann Arbor, Mich., read a paper with this title. The chemical products of putrefaction are modified by the conditions under which the process proceeds. There are always present, during life, in the upper part of the small intestines, certain anaërobic germs which produce indol and its derivatives. When the host dies, these germs do not necessarily cease to exist. They can grow, multiply, and produce their special products only in the absence of air. Pancreatic and hepatic tissues allowed to decompose in the absence of air, contain chemical substances which can be extracted by the methods of Draggendorf, and which give many tests similar to those given by morphine.

The author had demonstrated these facts by experiment. This being true, new methods must be sought for the detection of morphine in the human body after death.

No discussion.

Gastro-enteric Rheumatism.—DR. HENRY M. LYMAN, of Chicago, presented this communication. Gastro-enteric rheumatism is characterized by symptoms as definite as those of articular rheumatism.

It occurs among neurotic, arthritic, senile, or prematurely-aged people.

It belongs to the erratic and neuralgic variety of rheumatism.

Its pathology is as indefinite as that of chronic neuro-muscular rheumatism in general.

It is probably due to acidity of the stomach, or at least to the absorption of the products of an abnormal digestive process. The symptoms come on when the stomach is nearly empty, *e.g.*, at midnight. The pains are exceedingly variable, but are distinct from gastralgia. It is a dull, deep-seated pain, not influenced by motion. It shifts from place to place. It may be in the cardiac region, it may involve the pelvic nerves and cause rectal or bladder symptoms, or the sexual nerves and cause priapism. Unlike dyspepsia, it does not affect the general health, though the patient may become anæmic.

The treatment consists in providing warmth and dryness of the surroundings of the patient; hepatic and renal elimination; nutritious and easily digested food; warm baths, and abundant exercise.

DR. J. H. MUSSER, of Philadelphia, deprecated the introduction of new terms. He would prefer "the gastro-enteric form of lithiasis."

DR. J. E. GRAHAM, of Toronto, Canada, expressed his interest in the paper.

DR. VICTOR C. VAUGHAN, of Michigan, said: We use the term rheumatism to cover a great variety of things. We should make a distinction of those pains caused by uric acid. It might be well to call these pains described above, gout. He called attention to the fact that the tendency of investigators was to doubt the former teaching that uric acid was an incompleted stage in the production of urea.

DR. I. T. DANA, of Portland, Me., thought that rheumatism is a conglomerate pathological mass. He would confine the term rheumatism to acute articular rheumatism and give other names to other conditions.

DR. VAUGHAN agreed with the previous speaker, and added that he believed these diseases would ultimately be distinguished by examinations of the blood.

DR. LYMAN closed the discussion. He was not satisfied with the name, but it was the best he could do in the present state of our knowledge

Osteomalacia.—DR. GEORGE DOCK, of Ann Arbor, Mich., reported the case of a woman, aged twenty-five years, a native and resident of Michigan, who had a marked case of osteomalacia. The case was probably, though not distinctly, of puerperal origin. The case lasted three or four years, with marked symptoms for two and a half years, and was characterized by the common subjective symptoms and softening, spontaneous fracture, and deformity of the bones, and excretion by the kidneys of large quantities of lime salts (renal colic). Treatment had no influence on the disease (lime, phosphates, etc.).

Post-mortem.—The changes were very marked and do not throw any light on the pathology of the disease (microscopic and histological specimens were shown).

He referred briefly to all the cases hitherto reported in the United States, which, excluding three of doubtful diagnosis, are very few, and do not add materially to our knowledge of the disease.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 24, 1894.

GEORGE C. FREEBORN, M.D., PRESIDENT, IN THE CHAIR.

Carcinoma of the Head of the Pancreas.—DR. J. S. ELY presented such a specimen. A man sixty-three years of age, a shoemaker by occupation, was seen by him in March, 1892, with Dr. Ferrer, at the Out patient Department of the Roosevelt Hospital. He had been well up to six weeks before. At this time he began to have pain in the right hypochondrium, and detected a lump in this region. On March 3d, he rather suddenly became jaundiced, and four days later there was a severe attack of vomiting, the vomitus being whitish and free from blood. The pain in the region of the tumor continually increased, the tumor appeared to be growing larger, and he had lost much flesh and was greatly troubled with insomnia and constipation. When first seen, he was much emaciated and deeply jaundiced; the tongue was dry and clean, and the arteries hard and tortuous. A physical examination of the chest gave the signs of pronounced emphysema. On the right side was a large, irregular, nodular mass which appeared to be the lower border of an enlarged liver. The mass was quite tender and slightly movable on deep inspiration and gentle manipulation. No tumor could be detected under the enlarged liver, or in the situation of the pylorus. The stomach was normal in size. The temperature was 99.8° F.

The case was apparently one of carcinoma in the substance of the liver. Because of the absence of marked gastric symptoms and gastrectasia, and because of the intensity of the jaundice, he had been inclined to the opinion that the primary carcinoma was in the head of the pancreas, or in the common bile-duct near its entrance into the duodenum, the former being considered the more probable on account of the late appearance of the jaundice. After admission to the hospital the pain was relieved somewhat by moderate doses of morphia. There was quite free epistaxis on several successive days, and this greatly prostrated him, so that on March 23d, after a short period of unconsciousness, he died of exhaustion. During the two weeks he was in the hospital, the temperature was not higher than 101° F., and it only once reached that point four days before his death.

The autopsy was made by the speaker about twenty-four hours after death. The body was much emaciated and extremely jaundiced. Scattered through the mesentery were many small, hard masses, the largest being about half an inch in diameter. Many of these were situated at the point of attachment of the mesentery and intestine. Around the common bile duct was a hard mass, $1\frac{1}{2} \times 1 \times \frac{3}{4}$ inches, which replaced the substance of the pancreas. This mass was continuous with a thickened mass around the common bile-duct near its mouth. Above this point this duct was greatly dilated. Scattered through the liver were spherical masses—both discrete and conglomerate—which were very abundant near the

lower border of the liver. They presented the characteristic appearance of carcinomatous nodules in the liver. Between the nodules the liver substance showed dark centres and light peripheries of the nodules. The gall-bladder was adherent by old adhesions to the under surface of the liver, to the duodenum, and to the tumor around the mouth of the common bile-duct. The stomach appeared normal. The spleen showed chronic congestion and interstitial splenitis. The kidneys were of about the normal size; their capsules were moderately adherent; there were some small cysts, and the markings of the cortex were indistinct. There were numerous small ulcers, with indurated bases, situated on the mesenteric attachment of the small intestine, and continuous with the small tumors in the mesentery. The hemorrhage was thought to have occurred from some of these ulcers. The intestine contained much liquid, granular, dark greenish-brown fecal matter. The heart was of normal size. There was atheroma of the aorta. The lungs were excessively pigmented, and their surface showed considerable old pleurisy. Specimens were exhibited under the microscope showing intense athracotic pigmentation, lying in the interlobular connective tissue. This same pigmentation was also quite abundant in the liver—a point worthy of note. Scattered through the lungs were a dozen or more hard nodules, the largest being three fourths of an inch in diameter. Microscopical examination showed all the growths in the various organs, as well as the masses in the mesentery and intestinal wall to be deno-carcinoma, or that type of carcinoma in which the arrangement of the epithelial cells was such as to suggest the acini of a gland. This was not the appearance, however, everywhere, the tumor in many places presenting the typical picture of small alveolar carcinoma. The structure of the metastases was much more uniformly that of adeno-carcinoma than that of the supposed original tumor in the head of the pancreas. With regard to the intestinal lesions, there could be no doubt that the ulceration was a secondary result of the involvement of the intestinal wall by metastases which formed in the mesentery at the point of its attachment to the gut. The sections showed several stages of the encroachment of these metastases on the intestinal wall, and of the resulting ulceration. Intense congestion was visible in the floors of some of the ulcers, and it was undoubtedly from these that a part of the hemorrhage occurred, evidence of which was seen in the dark granular material filling the intestine.

The speaker said that the occurrence of such metastases, with secondary involvement of the intestine and ulceration, he believed to be rather unusual. The material giving origin to these metastases must have been carried by the blood-current.

A tumor of the structure and location here described might have its origin in the duodenum, in the common bile-duct, or in the head of the pancreas, and it was usually impossible to say with certainty from which of these structures it originated in the present case. But, as the head of the pancreas occupied the centre of the carcinomatous mass which, it was evident, was the primary nodule of the tumor, it was believed to have begun its growth in the pancreas. A measure of support was given to this view by the following case:

A man sixty-one years of age, a varnisher by occupation, was treated in the Roosevelt Hospital, during the fall of 1891, for chronic diffuse nephritis, and was discharged improved. On March 24, 1892, he returned, stating that soon after he left the hospital he began to feel weak, and to be troubled with cough in the morning, and occasionally by bloody expectoration, dyspnœa, and palpitation. On March 14th, he first noticed jaundice, and this had steadily increased. On admission he was deeply jaundiced and decidedly emaciated; there was œdema of the legs and thighs. The tongue was coated and dry, the arteries were very atheromatous, the pulse was 96, regular and feeble, and he had ascites. The temperature was 99°. Physical examination showed an accumulation of fluid in both pleural cavities, more on the left side. The hepatic dulness extended from the fifth rib to the free border of the ribs. He soon developed orthopnœa, and died on March 26th, four days after admission. The post mortem examination was made the same day by Dr. Ewell, the house physician. The abdominal cavity contained much bile-stained liquid, and the organs were also bile stained. The left pleural cavity contained fluid; the heart was somewhat enlarged, and the left ventricle dilated and hypertrophied. The mitral valve was thickened and calcareous. The lower lobe of the left lung was compressed and carneous, and contained a nodule of old healed phthisis, one-half inch in diameter. There was a similar nodule in the right apex. The peritoneum around the liver was covered with a layer of loose fibrin, and the gall-bladder was distended and filled with liquid bile. The cystic duct was apparently obliterated. The liver weighed three pounds and eight ounces, and was very hard, and the interlobular fibrous tissue was increased. The kidneys were small, the capsules adherent, the cortex thin, and the markings obliterated. The spleen was small and hard, and showed recent inflammation of its capsule, similar to that seen in the liver, besides old perisplenitis. The stomach, duodenum, and small intestine were normal. The head of the pancreas was hard near its tip. Behind this was an abscess-cavity, one and a half inch in diameter, and a second separate abscess was found in the tail of the pancreas. Microscopical examination of the hard mass showed it to be an adeno-carcinoma. The mesenteric lymph nodes near the pancreas showed no involvement, and there was no trace of metastasis anywhere. The death of this patient from Bright's disease and peritonitis, revealed a carcinoma in the head of the pancreas in a very early stage, while still limited to the original site.

The speaker said that he had reported these two cases that they might be compared with the one presented at the last meeting. Where jaundice developed in an old person in the manner described, and where gall-stones and inspissated bile could be fairly excluded, carcinoma at this point should be thought of as an extremely likely cause of the jaundice. In two of the cases the diagnosis was made of carcinoma in this region—a more exact localization would of course be quite difficult. In the first case, he thought, from the late development of the jaundice after nodules had formed in the liver, that there was probably a carcinoma in the head of the pancreas instead of at the mouth of the common bile-duct, in which case the jaundice would have probably occurred earlier.

Dr. J. M. Byron said that he was exceedingly surprised at the similarity of the structure exhibited in the various organs in which metastasis had occurred. It was well understood, of course, that in a glandular organ like the pancreas the growth might take place on the epithelium of the organ, and proliferate and produce a new growth which would resemble the organ from which it sprung; but when the metastasis occurred, for instance, from the pancreas to the bone, or to another organ not a glandular organ, he could not understand how a glanduloid formation such as was seen in the specimen could take place. This was the first time he had heard of it.

Regarding the second case, he asked whether the lungs had been examined, and also the exudation of blood, in order to determine whether or not there was a primary epithelioma of the pleural cavity.

Dr. Ely replied that he did not make the autopsy and had not been able to see the physician who had made it, but if there had been anything noticeable about the pleura he felt sure that it would have been noted. There was a great deal of œdema and advanced ascites, and it was thought at the time to be not an exudation, but a simple transudate.

Dr. Byron said he had asked this question because he was familiar with cases of endothelioma which had been presented by Dr. H. M. Biggs, and in which the first symptoms were those of small exudations of bloody se-

rum into the pleural cavity. These had been diagnosticated at first as ordinary pleurisy, but at the autopsy the pleura had been found to be greatly thickened, and there were immense numbers of metastases.

General Tuberculosis.—Dr. T. S. Southworth presented specimens from a case of general tuberculosis. They were removed from a child of fourteen months, in the Nursery and Child's Hospital. It was one of twins, and when born, in November, 1892, weighed 4½ pounds. It was breast fed, and did well up to the spring of 1893, when it had whooping cough. At the age of six months it weighed 16 pounds. Last August it began to have a slight cough, and since then it steadily failed, until at the time of its death, on January 18, 1894, it weighed only 8¼ pounds. The chest was examined once or twice by the house physician, but no very definite physical signs were found. At the autopsy the emaciation was very noticeable. The abdomen was distended. On opening the thorax the right pleura was found firmly adherent over the upper and middle lobes of the right lung, and there was a yellow, cheesy mass found beneath the pleura, embedded in the upper and middle lobes on the anterior surface. It was adherent to the pleura, but not to the lung tissue. When removed, it left a rough cavity which did not apparently communicate with the bronchi. The edges of this cavity were sharp and slightly overhanging. The upper and middle lobes of the lung were consolidated, and showed tubercles on the surface. The adjacent bronchial glands were large and cheesy. The left lung also showed scattered patches of tubercular infiltration. The pericardium was adherent over the left border of the right ventricle. The heart and valves were normal. The liver showed a few tubercles on the surface. There was general adhesive peritonitis binding together all the abdominal organs, but there was no fluid in the abdominal cavity. The spleen was covered with lymph, its capsule was opaque, and there were a few miliary tubercles on its surface. The kidneys were apparently normal. Both the large and small intestine were covered with lymph and studded here and there with tubercles beneath the peritoneum, and also in the mesentery. In the large intestine were some superficial ulcerations, and other areas which appeared to be suppurating lymph nodes which had not broken down. The mesenteric glands were much enlarged and cheesy. The nodule found embedded in the upper part of the right lung was about the size of a walnut. Smears were made from the deeper portions of the mass, and tubercle bacilli found. Small pieces were also examined microscopically, and showed cheesy degeneration and the remains of giant cells. There was no definite glandular structure remaining.

A Case of Pyuria.—Dr. F. Tilden Brown presented a report of a case for diagnosis. He said that he had had a patient suffering from pyuria under his care for five months. The patient had been bedridden for the greater part of this time. There was no abnormal temperature. The cystoscope showed pus coming from the left ureter. He had not been able to exclude tuberculosis of the genito-urinary tract, although repeated search had been made for tubercle bacilli. At times there was also a slight hæmaturia and some discomfort in the left side and left testis, suggestive of a renal calculus. The pain had been accounted for by the discharge in the urine of certain shreds. The hæmaturia had been rather more marked after exertion. The urinary examinations had been very contradictory. The speaker raised the question whether we could expect a tubercular process of the kidney where there was a profuse suppuration, and yet no associated micro-organisms and no elevation of temperature. He thought it would be rather unusual. If due to a stone in the kidney, one would expect more intense subjective symptoms. The leucocytes appeared to be well formed. He had examined for filaria, bilharzia, and similar organisms, with negative result.

Dr. T. M. Prudden remarked that in making examinations where tuberculosis was suspected, it was desirable to use the sediment from large quantities of urine. Lately he had been accustomed to ask for the urine of two or three days, and after decanting the sediment, it was placed in the centrifugal machine, and still further concentrated. By this method tubercle bacilli could be found in some cases where the more usual methods of examination gave only a negative result.

The Society then adjourned.

OUR LONDON LETTER.

From our Special Correspondent.

HOSPITAL SUNDAY—MANSION HOUSE RECEPTION—ROYAL SPEECHES FOR HOSPITALS—THE MIDWIVES' REGISTRATION QUESTION—THE ROYAL SOCIETY'S CONVERSAZIONE—THE ANNUAL MEETING—A DOCTOR'S LEGACY—OBSTETRICAL SOCIETY—DIVISION OF BROAD LIGAMENTS—EFFECT OF THIS AND OÖPHORECTOMY ON MENSTRUATION—OPPOSING OPINIONS—ADENOMA OF CERVIX WITH A DEPRESSION.

London, June 16, 1894

The Hospital Sunday Fund promises to equal past years, but at present only a small proportion has reached the Mansion House. Up to Thursday evening £14,000 had been received. The Lord Mayor and Lady Mayoress gave a reception on the 7th, in connection with the movement. Our princes have lately pleaded the cause of our hospitals. On Monday the Prince of Wales spoke for the Popular Hospital, and afterward inaugurated a new Home for Missions to Seamen. On Saturday the Duke of Connaught spoke at St. Thomas's Hospital, and it is very lately that the Duke of York presided at St. Mary's. This is good work for royalty.

The Midwives' Registration question continues to agitate professional circles, and Dr. Carter, of Liverpool, has entered the lists against Dr. Renton, who has so long waged war on behalf of the profession. Dr. Carter's previous appearances in medical politics are hardly calculated to inspire confidence in his proceedings or in those of the British Medical Association. It matters little, however, what may be done at present, for no one expects that the Legislature will find time to deal with the question this session, and the Government is not likely to add to its instability by attempting to pass a measure on a subject so much controverted.

On Wednesday last the *conversazione* of the Royal Society was held with the usual *éclat*. This function—sometimes called "the ladies' night"—is the one that appeals to the uninitiated, and therefore the one occasion on which the chief scientific society, so to say, unbends. There were a considerable number of photographs and other interesting things exhibited in illustration of various scientific matters. A curious if sombre exhibit was a mummy cloth calculated to have been made in the Fourth Dynasty, and the strands were said to be 300 by 150 per inch—a contrast with the 140 by 140 of present day fine Irish linen.

On Thursday the annual meeting was held, and the new Fellows elected. Among them are some whose work is of much interest to medical scientists, and two are members of our profession—viz., Mr. Watson Cheyne and Dr. J. Rose Bradford. The F.R.S. is so highly prized that I may venture to congratulate these gentlemen on the recognition of their work. It is always agreeable to see colleagues obtaining merited distinctions.

Another law case has been settled honorably to the profession. A will made by a sick patient left Dr. Ormsby £3,000, and this will was disputed on the ground of incapacity and undue influence. The case utterly broke down—"crumbled away," to use the expression of the judge—and the counsel for the complainants threw up his brief and publicly withdrew all

imputations But what is to compensate Dr. Ormsby for the expense to which he has been put and the moral torture he must have endured in the interim? It seems a terrible thing that a patient in dividing a property of £86,000 confers a doubtful benefit on his "dear friend and confidential adviser" by bequeathing him a moderate legacy.

At the last meeting of the Obstetrical Society a paper was read by Dr. Remfry, on "Ligature and Division of the Upper Parts of both Broad Ligaments, and the Result of this Operation as Compared with that of Removal of the Appendages." This plan was adopted in a case of bleeding fibroid, which did not admit of oöphorectomy. The paper compared the two procedures from an anatomical point of view as well as in reference to the result. In respect to the theories as to the amenorrhœa after removal of the appendages, the author, having discussed several, concluded that changes in the circulation with diminished blood-supply to the uterus were the chief factors; and this conclusion was supported by the case related, in which menstruation did not return for three months, and the slightness of the operation was opposed to the shock theory.

A decided difference of opinion was expressed in the course of the discussion respecting the amenorrhœa after oöphorectomy. Dr. Horrocks declared that in all his experience he had never seen menstruation continue for any length of time after complete removal of both ovaries. It is difficult to be sure that the ovaries are removed entire. He still held that the ovaries were essential to menstruation, although not to ovulation. He had never been able to find the nerve which was said by some to influence menstruation, and would like to see proof of its existence, but of course he did not doubt the influence of the nervous system. In contrast with this opinion Dr. Duncan said he had had four cases in which, many months after complete removal of the appendages, the patients had menorrhagia. He could not account for this unless the ligatures of the stumps were perhaps exciting irritation. He held that, so long as no ovarian tissue remained on the proximal side of the ligature, a small amount on the distal side was of no importance. In several cases he had left portions of firm ovarian tissue to prevent slipping of the ligatures, because the ovaries and tubes were so firmly matted down in the pelvis that he thought it safer to do so, but in no instance had menstruation occurred. Dr. Amand Routh referred to the possibility of hemorrhage from other causes, and said he had dilated in three cases of persistent hemorrhage after removal of appendages, and in two he had found a polypus and in the other villous growths. He believed the ovaries acted through ganglionic nerves going from them to the uterus, and, of course, these nerves were removed in oöphorectomy, so that we cannot absolutely ignore them as a cause of menstruation.

Dr. Routh's observation as to polypi is suggestive of the possibility of such cause being overlooked before oöphorectomy, and will no doubt put operators on their guard against such a mischance. Dr. Remfry's case, although interesting, is not unique, since, as mentioned by the President (Dr. Herman), a case has been recorded by Dr. Murphy and another by Dr. Kilner Clarke, and in them menstruation was not arrested. It has also been proposed to tie the broad ligaments in order to arrest malignant disease, but I do not remember to have seen it recorded that the plan has been adopted. Dr. Remfry, in his reply, did not admit that removal of the appendages insured the arrest of menstruation, some published cases being opposed to this, though it is not easy to refute the objection that in these cases the removal was not complete.

Dr. Braithwaite next read an account of a case of adenoma of the portio vaginalis uteri forming a depressed sore or ulcer. Drawings of the case were exhibited, and it was clearly an unusual one. Among the remarks made upon it I may mention that, except for the depression of the surface of the ulcer, every one would have taken it for an ordinary erosion and the suggestion that this depression might possibly be accidental, as erosion might have occurred on a previously depressed area. In support of this is the fact that the patient had had three children. Another suggestion was that the adenoma had become malignant where the ulceration had been seen, although the microscope did not show this. Still it is very common for these cervical adenomas to become malignant, and this change may begin in a very limited area.

STATISTICAL FACTS AND INACCURACY.

To the Editor of the Medical Record.

Sir: Referring to Dr. Spence's letter in the Record of July 7th, I must confess that I cannot attempt to unravel the garbling of my statements which it contains. I may, however, now quote from Dr. Spence's letter: "Statistics, in order to be valuable, should be, as to their material facts, correct."

Dr. Spence's doubts, to be euphemistic, hinge upon my Case IX. To show his correctness and minuteness, I may state that, on June 20th, the mother brought the child to my clinic at the Post-graduate School, and the case was shown to the students as practically cured.

Furthermore, I translate the following letters from Dr. Voegtle and the child's father (originals inclosed), lest Dr. Spence continues in his error, which I doubt not is unintentional.

The father writes: ". . . I never had the remotest thought of telling Dr. Spence that my child did not recover until Christmas. But I did tell him that the wound was entirely healed toward the end of July. . . ."

Dr. Voegtle, of Long Island City, writes, under date of July 10, 1894, ". . . Your dates regarding the case of empyema in Ravenswood are essentially correct, varying only in the matter of a day or two. . . . The child was discharged from treatment on July 16 (1893); the wound was healed in the beginning of July. . . ."

With the expression of most distinguished consideration to Dr. Spence, I am,

Yours very truly,

Carl Beck, M.D.

July 17, 1894.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 14, 1894.

	Cases.	Deaths.
Tuberculosis	95	100
Typhoid fever	17	6
Scarlet fever	57	9
Cerebro-spinal meningitis	2	3
Measles	59	4
Diphtheria	190	49
Small-pox	4	4
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Lancet's Investigation of the Electrical Treatment of Sewage.—The proposal to treat sewage electrically was received a few years ago with considerable enthusiasm, and many experts ventured to think that electricity, which was doing so many wonders in other respects, would probably also give assistance in the direction of sanitary affairs, and perhaps afford a satisfactory solution of the problem of sewage disposal, if not indeed of sewage utilization. But the

first attempts to utilize the electric current as a sewage purifier met with little success, owing to the great practical difficulties that were encountered. We need not enumerate them here. Suffice it to say that, of the electrical processes which count for anything now, there are two which continue to excite considerable interest and curiosity among engineers and sanitary experts at the present time. We refer to the Webster electrolysis process and the Hermite system of treating sewage with electrolyzed sea-water. In the former method the sewage is actually exposed to the action of the current, while in the Hermite method the sewage is submitted to the action of sea-water, the composition of which has been partially altered by the action of electricity. Briefly, the Webster process consists in allowing ordinary sewage to flow through channels in which are placed iron plates or electrodes, set longitudinally, with the usual battery connections, with the positive and negative terminals of a dynamo. The sewage in its passage through these channels is said to become entirely split up by the action of the electric current upon the chlorides always present in sewage. At the positive pole the chlorine and oxygen given off combine with the iron to form a salt, which is probably hypochlorite, and at the same time carbonate of iron is assumed to exist in solution, which not only deodorizes the fecal matter by removing sulphuretted hydrogen (FeS), but also acts as a carrier of oxygen from the air by being alternately reduced to ferrous and oxidized back to ferric oxide. The Webster process, therefore, although an electrical one, depends upon the production of certain chemical salts; but it is probable that the efficiency of the method depends largely, if not entirely, upon the fact that the sewage is presented to these chemical bodies while they are in a very active state—in fact, *in statu nascendi*. The Hermite method consists in the electrolysis of sea water and the subsequent flushing of the contents of water-closets with a definite quantity of the resultant fluid. The Hermite fluid is, therefore, a chemically active fluid, prepared by electrical means. The sewage is never in contact with the current, as in the Webster process, nor does the process pretend to secure the precipitation of organic matters. It claims, rather, to effect the complete deodorization and sterilization of sewer contents. Both processes, therefore, have one common object in view—namely, the healthy disposal and not the utilization of sewage.

The Hermite process for the treatment of sewage, with which the present report proposes to deal, has been conducted on an experimental scale at Worthing during the early months of the year, with the view of its adoption in accordance with the plan originated by M. Hermite.

The Lancet's communication has shown that electrolyzed sea-water contains probably as its chief active constituent hypochlorous acid, resulting from the partial dissociation of magnesium hypochlorite, and that it is fairly stable under ordinary circumstances; that it is a powerful bleaching liquid, being superior in this respect to bleaching powder solution, but not to a solution of bleaching powder of equal chlorine value, in which the hypochlorous acid has been liberated by the addition of a weak acid (CO_2 or others, in weak solution); that it is also a powerful deodorizer, and that in all probability these properties are due to the united action of oxygen *in statu nascendi* and chlorine. These, in brief, are the chemical properties of electrolyzed sea-water, and it remains for us to consider what effect for good or for evil such a liquid of definite strength would have when mixed in a certain proportion with fecal matter. It deodorizes, but does not destroy or remove organic matters, although there is little doubt that certain of them are partially changed, and most probably those which are more readily putrescible (*vide* the analysis of effluent). While these things are true and are so far satisfactory, there must also be certain drawbacks in the system which are likewise indicated in these experiments. Electrolyzed sea-water, for instance, is rapidly reduced in strength by common newspaper, and as this is an almost invariable accompaniment of human dejecta its presence in the sewer must seriously affect the activity of the liquid, even if it does not withdraw the active constituent entirely. Indeed the entire contents of a sewer rapidly appropriate the chlorine strength of the liquid. (Compare also in this regard the bacteriological experiments with stools, urine, culture, etc.) The same observation applies to soap or domestic waste, etc., which rapidly "kills" oxygenated chlorine compounds. Again, it can only be supposed that deodorization, not to say sterilization, is complete when the chlorinated body is in excess, and an effluent containing free chlorine or its equivalent is inadmissible to rivers. The expense, moreover, in inland towns would be greater since it would be necessary either to carry sea-water or to prepare it artificially. M. Hermite's proposal is to establish a producing centre in the towns and to supply the liquid through pipes into all the streets and houses, much in the same way that water and gas are at present supplied. The adoption of such a scheme in any place would no doubt lead to a sanitary condition of things hitherto unreached, but many excellent advances could be made in the same direction, it should be remarked, if cost were not an item which so often bars the way. Apart, however, from such a scheme, there is no doubt that the production from sea-water of a powerful bleaching agent and deodorant is an innovation which should afford very material aid to sanitary progress. Thus for many purposes the substitution of electrolyzed sea-water for other and more expensive agents in our sea-side towns and villages would doubtless confer many advantages. It could be used, for example—with desirable effect doubtless—to flush the headings of drains and sewers; it could be discharged into sewage outfalls; and, lastly, the system could be applied on a small scale for the sanitary treatment of hospitals, barracks, etc., by means of an automatic electrolyzer worked from a central electric supply. It should be added that, except as regards what has already been published in our columns, no particulars in regard to the actual cost of production have as yet been furnished by the originator of the main idea.

An Interesting Law Case.—An action for damages has just been tried in one of the Paris courts which perhaps is unique of its kind. A gentleman suffering from anæmia of a very hopeless type was advised by his medical attendants to submit to the operation of transfusion; and having consented, his gardener volunteered to supply the blood. Consequently transfusion was performed, and to the great benefit of the patient, who recovered completely after a short time. However, some time afterward the gardener fell ill, and attributed his condition to the sacrifice he made for his employer. He accordingly brought an action against him for damages, claiming the large sum of 60,000 francs, or nearly two thousand five hundred pounds. The court ordered an independent medical examination of the case; but in the meantime the man died, that is to say, two years and three months after the operation. The autopsy proved that the gardener had succumbed to a carcinoma of the stomach, and the doctors gave their opinion that the malady was not affected by the transfusion. However, the widow continued the suit, and last week the court dismissed the case with costs against the plaintiff.—*Medical Press.*

Physicians as Pioneers in Temperance Reform.—At the annual meeting of the British Medical Temperance Association on May 22d, Dr. Norman Kear said that, more than a hundred years before the beginning of the modern temperance reformation, the voice of medicine, by Dr. Baynard, in 1702, thundered against the milder intoxicant liquors. He characterized ales as "unwholesome and dangerous liquors," and suggested the making their sale criminal. A quarter of a century later Dr. George Cheyne, of Bath, commended abstinence as natural, healthy, and safe, and denounced moderate drinking as "unhealthy and dangerous." In another quarter of a century, in the *Universal Pharmacopœia*,

Dr. James (1747) approved the wisdom of Mahomet in forbidding fermented liquors to his followers. Seven years before the dawn of the nineteenth century, Benjamin Rush taught that no nourishment and no strength were found in spirituous beverages, followed a year later by Erasmus Darwin, who stigmatized wine as a pernicious luxury, injuring thousands. In the first days of the present century Beddoes declared that wine, constantly taken moderately, was mischievous and enfeebling; immediately after whom Trotter, while also declaiming against wine, reprobated beer as a poisonous morning beverage. Over sixty years ago Physician-General Cheyne ardently championed abstinence, as did Dr. Daniel Richmond, of Paisley, who was one of the founders of one of the first teetotal societies in 1832. To these pioneer temperance champions fell to be added, prior to 1876, when the British Medical Temperance Association was founded, among a host of medical abstainers, such outstanding men as Professor Rolleston, of Oxford, Menzies and Burn, of Edinburgh, Kirk, of Greenock, Linton, of Aberdeen, McKenzie, of Inverness, Grindrod, of Manchester, Beaumont, of Bradford, Higginbotham, of Nottingham, Fothergill, of Darlington, Collenette, of Guernsey, Clay, of Manchester, Mudge, of Bodmin, Thompson, of Bideford, and Henry Munroe, of Hull. Though the medical profession had often been abused for opposing the temperance cause, it was remarkable that from the ranks of medicine had gone forth unsparing condemnation of beer and wine before the early temperance pledge of abstinence from ardent spirits alone had been publicly proclaimed. In proof of the sympathy of medicine and surgery with temperance, Dr. Kerr cited the three great medical declarations on alcohol, the first in 1839, given by Julius Jeffreys, the second in 1847, by John Dunlop, the third in 1871 by Mr. Ernest Hart and Mr. Rae.—*British Medical Journal.*

Therapeutic Wisdom.—The *American Druggist* says that among the queer collection of stolen and confiscated goods, in the private office of Police Inspector McLaughlin, is a medicine chest containing six compartments, each with five small bottles from "Caswell & Massey." On the inside of this case, written in Gothic text, was this stanza:

> For every ill under the sun
> There is a remedy or there's none.
> If there's one, try and find it;
> If there's none, never mind it.

Some New Methods of Treating Diseases of the Stomach and Intestine.—Rosenheim (*Berl. Klinik*, May, 1894) first discusses the stomach douche. He uses a tube with numerous side-openings and one larger terminal opening. Under pressure the water issues from all these orifices, and in this way all parts of the stomach are acted upon. The douche is used morning and evening. By this method syringing with force against the stomach-wall is avoided, and by using the douche when the stomach is empty, matters serving for nutrition are not abstracted. The douching is more easily done by the patient, and the tube does not get blocked. Besides warm douches, which are sedative and but slightly stimulating, water containing common salt, chloroform, silver nitrate (1 in 1,000) may be used. The douche is useful in nervous dyspepsia, chronic gastric catarrh of moderate severity, and in severe affections of the sensory and secreting apparatus of the stomach, as in gastralgia, hypersecretion. The addition of sodium chloride to the fluid is said by the author to increase the HCl production, and that of silver nitrate to diminish it. After the stomach is washed out once or twice, the silver solution is run in and allowed to remain half a minute. The procedure is unattended with danger provided the pylorus be not incompetent. The pylorus is rarely incompetent, and this is readily ascertained by blowing the stomach up. As regards the electrical current, the exact indication as to the kind is still in doubt. For motor insufficiency, the value of electrical treatment is unquestionable. The author thinks it also allays sensory irritation symptoms; galvanism should be used here with the negative pole in the stomach. He then speaks of recto-abdominal galvanization in cases of motor weakness of the intestine. A case is cited to show the value of electricity even when the irritation symptoms and pain in the stomach are due to organic disease, probably a cicatrized ulcer The author then discusses the treatment of gastric ulcer with large doses of bismuth. He gives ten grains of bismuth subnitrate in two hundred grains water in the morning on an empty stomach, and fifty grains of water are drunk a little later. Finally, the author speaks of the treatment of spastic constipation by large oil clysters: four hundred to five hundred grains of pure oil are injected, and this is followed, if necessary, by a water enema later; the injections are given daily at first. Instances are given of the good results of these various methods of treatment.—*British Medical Journal.*

The Cause of Cancer.—The weight of evidence seems to point, then, to the "sporozoa" as nothing more than degeneration products of the epithelial cells. This view is held by the majority of those who have studied them, and is supported by the irregular shape and occurrence of the bodies, by the well recognized tendency of the cells of carcinoma to undergo degenerative changes, by the more abundant occurrence of the bodies in the medullary variety of carcinoma in which the degenerative changes are most frequent, and in the epitheliomata (flat-celled carcinomata) of the skin in which more or less ulceration and degeneration have been present. The nature of the degeneration is undoubtedly different in different cases. Some of the appearances are explained as the result of degeneration of the nucleus, some as the result of degeneration or vasculation of the cell body, and some as the result of penetration of leucocytes, red corpuscles, or other cells into and between the bodies of dead or degenerate cells of the tumor. Stroebe concludes that, while a possible parasitic origin of carcinoma cannot be definitely denied, there is as yet no positive evidence whatever in favor of such a view.—*American Journal of Medical Sciences.*

Worse than the Climate of Colorado must be that of the Himalayas, if one may generalize from the experience of Mr. Conway in that region. In a recently published book on "Climbing and Exploration in the Karakoran Himalayas," in speaking of the rapid changes of temperature, he relates the experience of his party. One morning, on the way from Gargo to Gilgit, they encountered a violent storm. The wind blew a gale, the snow was so thick as to darken the sky, and the cold was intense. Suddenly "the wind ceased, the sun came over the edge of the hill and drove the frost away; the brook began to tinkle again, a cuckoo called from the birch scrub across the glacier, and a bumblebee droned around the tents. A more sudden change it would be impossible to imagine. The sun was soon too hot, and within two hours the temperature—which had been down to 15° F.—rose to 80°."

A Good Fee.—The barber who cut Louis XIV. for fistula in ano received a present from his grateful patient of $60,000, a fine estate, and a patent of nobility.

Woman Is Not Fit to Practise Medicine; she is not fit for the elaboration of the arts and the enlargement of the sciences, nor is she fit for politics. To prevent misconception we hasten to add that these are the words of Dr. Abeken, of St. Louis, and not ours.

The French Language in Japan.—The foreign professors in the medical department of the University of Tokio are chiefly Germans, and the students are obliged to learn that language. Until recently, says *l'Union Médicale*, they were also required to learn English, but they have now requested the government to allow them to learn French instead of English, giving as the reason for the change that "Pasteur and Charcot have no equals in England, and they (the students) wish to be able to read the works of these two savants."

CASES OF OSTEOPLASTIC RESECTION OF THE SACRUM.

BY FRED. KAMMERER, M.D.,

SURGEON TO THE ST. FRANCIS AND GERMAN HOSPITALS, NEW YORK CITY.

IT is now generally admitted that the only way of dealing effectively with certain ailments of the rectum, especially its upper parts, is by approaching the seat of disease from the posterior wall of the pelvis. It is possible that after greater experience with the technical difficulties of the methods based on incision of the soft parts only has been gained, the latter may rival those procedures, which require the permanent or only temporary removal of parts of the bony structure of the pelvis as a preliminary measure. At present this is not the case. The exposure of the rectum from behind, with removal of the coccyx and part of the sacrum, is still regarded by most surgeons as better adapted to the end in view than simple incision in the parasacral region (Woeffler) or through the soft parts lying between both tuberosities of the ischium (Schelkly).

Since Kraske's publication, about eight years ago, quite a number of modifications of the original have been proposed.

At first the plan of removing permanently parts of the sacrum and the coccyx seemed to be most in favor, some difference of opinion existing among surgeons as to the line of incision through the bone. Thus Kraske originally removed besides the coccyx that part of the sacrum on the left side lying below the third and including the fourth sacral foramen, but not extending to the middle line (*a b c*). Hochenegg modified Kraske's incision to include part of the right half of the sacrum (*a d*), and Bardenheuer recommended transverse section of the bone below the third sacral foramina (*a e*, Fig. 1). Even after removal of so large a

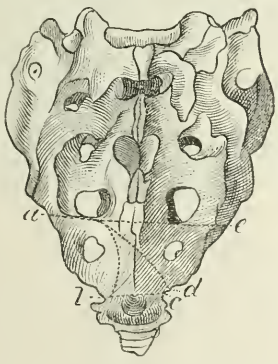

FIG. 1.

piece of bone as in Bardenheuer's operation, very little discomfort, if any, has been experienced by the patients who have recovered from these operations. As drawbacks of these methods by which parts of the bone are sacrificed, have been mentioned weakening of the floor of the pelvis, interference with the functions of bladder and rectum, loss of the point of attachment of the sphincter ani muscle at the tip of the coccyx with consecutive disturbance of the function of that muscle and kinking of the rectum, due to contraction of the cicatricial tissue about the end of the divided sacrum. In a former article [1] I mentioned that I had not myself observed any of these symptoms after removal of the lower end of the sacrum, but others have occasionally seen them. On the whole, I believe they are very rare. We should therefore demand of the osteoplastic methods that they possess technical advantages, if they are to be preferred to the more radical measures just mentioned. Is this really the case? It does not seem to apply to the methods of Hegar, Kocher, and Levy. These are technically more difficult, and are said by others to unnecessarily complicate wound treatment. I cannot, however, speak of them from personal experience. I was, on the other hand, more favorably impressed by the plan, which Rydygier [2] recommended about a year ago, and after giving it

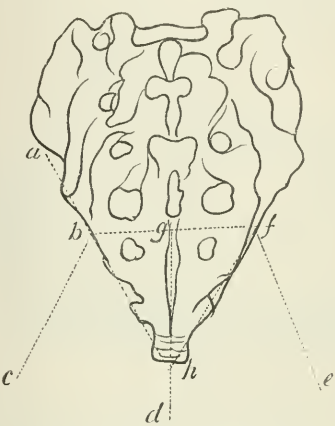

FIG. 2.

a trial in six cases, prefer it to either the methods of Kraske, Hochenegg, or Bardenheuer, which I have formerly employed. Fig. 2 shows the various incisions through the sacrum for temporary removal of the lower end of that bone and the coccyx. Hegar's incision, *d h b f*, separating the bone but not the soft parts in the line *b f*, has for its object the elevation of the flap *b f h* on *b f* as an axis. Kocher splits the coccyx and sacrum in the median line and then adds a transverse section of the bone (*h g f*, *h g b*), turning the flaps thus formed to both sides. Levy makes a transverse incision (*b f*) over the sacrum and from its ends adds two further incisions running downward and outward (*b c*, *f e*). After dividing the bone in the line *b f* the flap is turned downward. Rydygier incises the soft parts, beginning at the posterior superior spine of the ilium on the left side and running down to the tip of the coccyx, thence in the median line to the anus (*a b h a*). After division of the sacro-sciatic ligaments, the soft parts are removed from the anterior surface of the sacrum by the hand of the operator. A transverse incision is then added below the third sacral fora-

[1] MEDICAL RECORD, February 20, 1892.
[2] Centralblatt für Chirurgie, No. 1, 1893.

mina (*b f*) and the bone divided along this line with a chisel. The flap *f b h* is now turned to the right side, upon *h f* as an axis. With a retractor inserted at the tip of the flap (*b*) the latter can be easily held aside and manipulations about the rectum can be as readily carried on as when the bone has been entirely removed.

Case I.—M. A. S——, aged forty-two; native of Ireland. In the summer of 1892 she began to suffer from tenesmus and bloody stools, and was treated for hemorrhoids. The nature of her complaint being later on recognized, she was sent to St. Francis Hospital for operation. On examination a cancer of the rectum was discovered, beginning immediately above the sphincter ani on the posterior wall, occupying the lateral walls of the rectum, but leaving a small portion of the anterior wall of the gut intact, into which the exploring finger could be barely placed. The upper end of the neoplasm was not reached.

March 22, 1893.—Rydygier's osteoplastic resection of the sacrum in the knee-elbow posture, in the presence of Dr. E. W. Cushing, of Boston, and Drs. William Polk and George Edebohls, of this city. Very slight hemorrhage during incision of the soft parts, only a few ligatures being necessary. Division of the sacro sciatic ligaments. It was then a very easy task to separate the soft parts from the anterior surface of the sacrum with the aid of the index-finger, keeping the latter well against the bone. The transverse incision was carried immediately down to the bone, and a chisel about an inch wide was employed in severing the latter, beginning at the left border and moving the instrument over the posterior surface of the sacrum to the right. With a few strokes of the mallet the bone was very quickly divided. After elevation of the flap to the right and dissection of the tissue covering the rectum, it now became apparent that it was impossible to save the sphincter ani. The anus was, accordingly, circumscribed by a new incision and the entire lower end of the rectum separated from the surrounding tissues. After free incision of Douglas's pouch and further separation of the rectum as far as the promontory of the sacrum, more especially after incision of the lateral folds of the peritoneum, forming the reflection from the sacrum upon the rectum, the gut was easily drawn down, so that the tumor lay well outside the anal opening. After the closure of the peritoneum with interrupted catgut sutures, amputation of the rectum was done about three-fourths of an inch above the border of the tumor and the end of the gut sewed to the margin of the wound at the site of the normal anus. Iodoform-gauze tampons were then placed upon, and to each side of, the new rectum, their ends protruding from the wound-cavity just above the new anus. The flap was now returned and everywhere united by sutures of silk-worm and cat-gut, excepting the parts where drainage was to be established by the gauze leading from the wound-cavity. Dry aseptic dressing externally. The tampons were removed for the first time on the fifth day, the external dressings having been changed quite frequently. Primary union occurred throughout the sutured area. Recovery uninterrupted. Complete cicatrization at the end of the sixth week. Length of the amputated portion about five inches.

September, 1893.—Removal of a small recurrence between rectum and vagina.

April, 1894.—Patient in fair health (Fig. 3 shows condition of external parts). There is now a recurrence on the posterior wall, for which the patient will allow no further operative interference. There is apparently firm union of the bone at the site of division and the appearance of the parts externally is, but for the line of union, normal.

Case II.—G. R——, aged sixty-eight. Has been complaining of rectal trouble for the past two years (pain during defecation and hemorrhages). Large circular cancer of the rectum, mostly on anterior wall, several inches above the anus. Cachetic appearance. Very marked atheromatous degeneration of arteries.

April 26, 1893.—Osteoplastic resection. Flap dissected up, as easily as in first case; no hemorrhage to speak of; resection of rectum after enucleation of the same from the surrounding tissues; division of the rectum below the tumor, leaving about two inches at the anal end; incision of the peritoneum; resection of about four inches of the gut; suture of the divided ends

Fig. 3.[1]

with catgut; extirpation of many sacral lymphatics which are involved; drainage with gauze; flap replaced and sutured as in first case. Profound collapse after operation, from which the patient rallies well in a few hours. Early the next morning he very suddenly expires shortly after drinking. Autopsy not allowed.

Case III.—A. B——, aged twenty; married. Nine months ago, double salpingo-oöphorectomy was done in this city, in consequence of which a fecal fistula remained. When first seen at the German Hospital in September, 1893, was in poor general condition. Several fistulous openings, from which pus and fæces came away, were found in the cicatrix of the abdominal incision. They all led to a subcutaneous abscess cavity, which in its turn, when incised, communicated at the lower end of the original incision with the gut through a long fistulous track, leading downward and backward into the pelvis. A probe introduced into the fistula passes to the left of the uterus and vagina, but the point of communication with the rectum cannot be found. Feeling assured, however, that it did exist and that, on account of probable adhesions, it would prove a hazardous undertaking to attempt reaching the seat of trouble by an anterior incision, I decided to do osteoplastic resection of the sacrum and thus to get to the opening in the gut.

The operation was conducted as in the other cases, with the only exception that the patient was placed on her right side, with flexed lower extremities and elevated buttocks. Considerable hemorrhage occurred and there was a good deal of delay on this account in elevating the flap. Introducing a probe into the fistula, the point of which could be felt from the posterior wound high up on the anterior surface of the rectum, I attempted to reach this point by dissecting off the rectum on the left side. While thus occupied, the patient went into a deep collapse, which necessitated immediate interruption of the operation, from which she only fully recovered after many hours. The wound-cavity had been hurriedly tamponed and no sutures were applied to the flap. In the course of the following two months the cavity gradually filled with granulations and the flap fell into place. At the end of this time the flap was again raised and the

[1] Dr. Fischlowitz, house-surgeon of the German Hospital, has very kindly taken the photographs used in this article for me.

same plan pursued in attempting to reach the opening in the rectum. After much labor I finally came upon a small cavity, the size of a walnut, on the anterior surface of the rectum, far above the plane of Douglas's pouch. There I found the point of the probe. I could just reach the cavity with the tip of my finger, but could not find the intestinal lesion. A tampon was pushed down into the cavity in the hope that it might heal by granulation and the fistula thus close. The entire line of incision was again left unsutured. The wound has filled with granulations. No more fæces have escaped during the last two months, either by the anterior or posterior fistula, both of which still exist, however, but are apparently closing. The incision along the left border of the sacrum is still open for about two inches, and several attempts to close it by secondary sutures have failed. The general condition of the patient is excellent.[1]

Case IV.—J. F——, aged forty-five, recto vaginal fistula in the upper part of vagina after extirpation of the uterus for cancer. An attempt to close the same from the vagina failed and the patient was transferred to my service at the German Hospital for osteoplastic resection of the sacrum. Knee elbow posture; after elevation of the flap the fistula was exposed by separating the tissue to the left of the rectum. Considerable difficulty was experienced in separating the rectum from the vagina; when this was accomplished the edges of the large opening in the vagina were excised and the opening itself carefully sutured; an iodoform tampon was introduced, but the opening in the rectum was left unsutured. The flap was returned, and the transverse and the vertical incision below the coccyx were united by sutures. That part of the incision lying to the left of the sacrum was left open, and from it the tampon protruded. The latter was left undisturbed for eleven days, when the bowels were moved for the first time. Very soon the introduction of the tampon to the site of the old fistula became difficult, as the wound-cavity began to cicatrize very rapidly. However, while there appeared to be union in the vagina, some fæces were naturally discharged by way of the tampon through the wound-cavity and opening in the rectum.

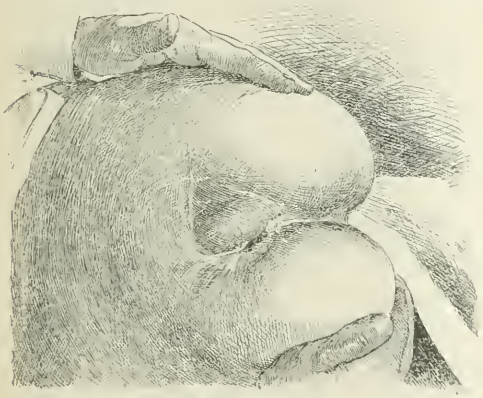

Fig. 4.

At this time it became apparent that a small fistula had again formed in the vagina Fig. 4 shows the condition of the external parts three months after operation. The opening to the left of the sacrum for the tampon is the only portion of the original incision which has not closed. I now intended to make an artificial anus and to again elevate the flap later on, but I abandoned this idea on discovering extensive secondary infiltration of the lymphatic system of the pelvis. The wound has not entirely closed yet, about four months after operation, but no fæces escape from it, and only when the movements are liquid does fecal matter escape from the vagina.

Case V.—H. B——, aged fifty-eight. For the last two years blood in stools and lately great difficulty in defecation; general condition poor. Two and a half inches from the anus a cancerous growth, almost entirely occluding the lumen of the rectum, through which the examining finger cannot be passed.

December 21, 1893.—Left inguinal colotomy. Following this for several weeks irrigations of the rectum, three or four times daily, from anus through the colotomy-wound.

January 18, 1894.—Osteoplastic resection of sacrum in knee-elbow posture. Resection of three and one-half inches of the rectum, after incision of Douglas's cul-de sac; about one and one-half inch of the anal end is left, which is sutured to the upper end of the rectum in its entire circumference; flap returned and sutured throughout, with exception of opening for drainage below the coccyx. The peritoneal cavity was not closed by sutures in this case, but tampons of gauze, placed to each side of the rectum, were brought well up to Douglas's pouch. Uninterrupted recovery. Primary union, with exception of posterior circumference of the sutured gut, where separation and slight sloughing occurred (Fig. 5). At the end

Fig. 5.

of March a small opening was still present below the coccyx, which communicated with the rectum and marks the spot at which the rectal sutures gave way. Here there is a stricture of the gut.

March 30th, flap again raised. Excision of stricture. Finding it impossible to unite the two ends of the rectum on account of tension, the plan, recommended by Dr. Lange of this city, of transplanting the anus upward and backward after a transverse incision in the perineum between both tuberosities of the ischium was adopted. After carrying the incision well up between vagina and rectum, the anus could be moved for about one and one-half inch, making suture of the approximated ends possible. The transverse incision in the perineum was united with silk-worm gut in a longitudinal direction. After the flap was again returned the anal orifice was found immediately below the coccyx. The anus has remained *in situ*, but some separation occurred in the perineum. The artificial anus still remains to be closed.

Case VI.—S. R——, aged seventeen. Always well as a child. Four years ago severe attack of diarrhœa, with frequent repetitions of the same during the following two years; then constipation, with much straining during defecation and loss of blood and mucus. Anæ-

[1] The posterior incision is now about entirely closed, three months later.

mic and emaciated girl. Beginning about three or four inches above the anus and extending upward, as far as the finger could reach, were a large number of polypoid growths. Left inguinal colotomy on December 18, 1893. Just below the longitudinal incision into the gut a polypus about one and one-half inch long and measuring about one-half inch in its widest part, with a very slender pedicle, is found and removed. Microscopical examination by Dr. Schwyzer, assistant pathologist to the German Hospital, showed it to be an adenomatous polypus.

January 20, 1894.—Osteoplastic resection of sacrum in knee-elbow posture. Longitudinal incision of the rectum, beginning about four inches above the anus and running upward for two or three inches. The entire mucous membrane lined with small and large growths of the kind described, as far as the finger can be passed upward in the gut. Finding it impossible to remove the growths individually, on account of hemorrhage and, above all, their location, I removed what I could with a long and large Volkmann spoon and tamponed the rectum, as hemorrhage during this manipulation was quite alarming. No suturing of the flap; tamponade of the wound cavity with sterilized gauze; marked collapse, but patient rallied well. Iodoform tampon in rectum removed on the fourth day for the first time, after which the temperature, which had ranged from 101° to 102.8° F., dropped to normal.

March 2, 1894.—Closure of the artificial anus and of the longitudinal incision in the rectum. For the latter a good deal of dissecting out of the rectum was necessary;

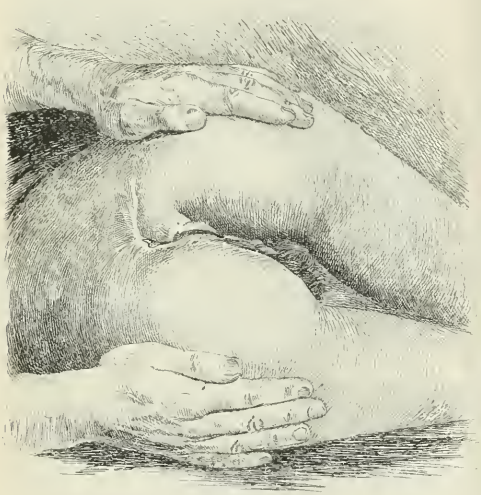

Fig. 6.

silk sutures, tampon of sterilized gauze. On April 6, when it is evident that perfect and firm union has occurred in both places, the resection flap is finally returned to its original position and retained there by several strong silk sutures. These sufficed to keep it in place, the anterior surface of the sacrum having meanwhile become adherent to the rectum. The original incisions are still granulating, but will no doubt soon close (Fig. 6).

The improvement in the patient's condition is very marked. The hemorrhages from the rectum have ceased entirely, and there is no pain during defecation, which occurs normally. The patient has gained very much in weight.[1]

In all these cases I have been impressed by the rapidity with which this preliminary operation can be done. While deprecating in general any time limit in surgical work, it is surely an advantage to accomplish something in from five to ten minutes, which otherwise requires a longer time, at least in my own experience, and that with decidedly less hemorrhage. I fully endorse Rydygier's claim, that his osteoplastic resection is a much less bloody operation than the permanent removal of coccyx and sacrum by any one of the other methods with dissection of the soft parts from the posterior surface of the sacrum. In only one instance of osteoplastic resection did I meet with considerable hemorrhage, in Case III., where I operated in the lateral position. I consider the knee-elbow posture, which I employed in all the other cases, with distinct elevation of the pelvis, especially of the sacral region, as the most desirable one for rectal surgery, since it controls hemorrhage through elevation, gives excellent access to the field of operation, the surgeon standing between the slightly separated thighs of the patient, and facilitates manipulations with the chisel, the pelvis being supported by sand bags placed under the anterior iliac spines.

When the flap, including the coccyx, part of the sacrum and the integuments, can be, from the nature of the case, returned to its place and sutured, the result will be an ideal one as regards restitution of the normal contour of the sacral region, as shown in Figs. 3 and 5. In suturing the transverse incision I have always passed the needle down to the bone, but have never included the bone itself in a suture, by any device whatever. Notwithstanding, in several cases in which I have had to elevate the flap a second time, I have always found firm union of bone surfaces, either fibrous or partly osseous. It is unfortunate that secondary operations so frequently become necessary in rectal surgery, for, even when we have resected the rectum and made a circular suture of the ends, we frequently find that the latter gives way on the posterior circumference of the bowel. Such, at least, has been my own experience and the experience of others as well, I believe. I have not, however, found the operation of raising the flap a second time any more tedious than the first. Greater care must only be exercised to avoid the rectum, which now has been drawn close to the anterior surface of the sacrum by cicatricial contraction. But I think, when we are dealing with cases, such as fistula for example, where tamponade of the wound-cavity becomes necessary for some time, we should resist the temptation of suturing the flap and we should leave the wound-cavity entirely open. My attention was forcibly directed to this point by Case IV. (Fig. 4), where I got very good union of the transverse and vertical incisions, but in which case a successful tamponade of the deep wound-cavity (about six inches) was not easily effected through the small opening corresponding to the unsutured part of the original incision. I think this fact was responsible for the ultimate re establishing of a small vaginal fistula. Such wounds ought to heal from the bottom of the wound-cavity to avoid even the slightest retention, endangering the object in view, and the best guarantee for this is a wide opening, allowing free inspection and tamponade.

Where no sutures are used some retraction of the flap develops after a time. This is no doubt much less than in flaps that are without a bony substratum. Even when only the lateral incision to the left of the sacrum has remained open (Fig. 4) a distinct elevation of the soft parts over the sacrum results from the same cause, a deformity which can, no doubt, at the proper time be very readily remedied by an insignificant plastic operation. This is not so readily accomplished when no suturing at all has been done. There is another fact worthy of consideration in this connection. It is this: After some time secondary operations on the rectum are even more difficult than the original ones, owing to the development of much cicatricial tissue about the gut, which makes the latter more rigid and does not in consequence permit the approximation of such parts which we may desire to unite by sutures. From all this we may conclude that it will

[1] I have just seen the patient three months after the above was written. She continues in excellent health. There is still a point of granulation to heal, but no fistula.

be wise to do secondary operations as soon as the condition of the patient will permit.

The cases of fistula which I have reported have not been entirely cured. They have been much benefited, however, and one of them is very likely closing. I firmly believe that in no other manner ought these cases to have been approached, certainly not by an anterior laparotomy.

While technically difficult, the sacral route is still the easiest way to get at the seat of disease when the rectum is affected, and also in some cases in which the uterus is to be dealt with. Rydygier's preliminary operation is certainly well devised, and being as simple as the permanent resection of the sacrum, while not disfiguring, assuredly deserves preference.

A CASE OF ACUTE SOFTENING OF THE BRAIN.

By PHILIP ZENNER, A.M., M.D.,

CINCINNATI, O.

CLINICAL LECTURER ON DISEASES OF THE NERVOUS SYSTEM IN THE MEDICAL COLLEGE OF OHIO.

DR. DILLER'S case of acute softening of the brain, published in the MEDICAL RECORD of April 28th, leads me to report the following case, which was also, for a time, believed to be one of hysteria, and in which, as in Dr. Diller's case, the paralytic manifestations were very slow in onset. I regret that my notes of the case are not more complete.

Mrs. S——, aged fifty-three. A brother and sister died of paralysis. She was always in good health until forty-six years of age, the time of the menopause. At this time, too, her husband had a long and serious illness, and underwent a dangerous operation, all of which doubtless assisted in developing her subsequent nervous malady.

One of the first physicians whom she consulted for her nervous symptoms—headache, vertigo, etc.—told her that she had a brain tumor, a diagnosis which was supposed to have had a permanently ill effect upon her; at least she was thereafter in constant dread of organic nervous disease. She never regained her former good health.

It is difficult in a few words to give a clear idea of the varied symptoms presented during the seven or eight years of her invalidism. Her chief complaint was of various paræsthesias, tingling sensations or the like, which never left her altogether. At first they were only in the left hand and arm, subsequently they were in the right arm or both arms, and in the face. Such sensations in the mouth prevented her from wearing her false teeth with comfort, so that for several years she did not wear them at all. Very often she would say there was no strength in her hand, she would not cut her meat, etc., though there was no evidence of paralysis.

At one time when I was called to see her I was informed that for months she had been unable to write. On questioning her she could not tell why, could only say she was unable to write; and seemed very much rejoiced when by a firm order on my part I succeeded in getting her to write. The same was true of reading. Often for months she said she could not read. She often had a peculiar disturbance of speech, something similar to aphasia; she would have to grope for words or sentences, speak only short sentences or only a word or two, and then halt as if unable to proceed farther. She would sometimes use the wrong word. But she could always give the name of an object or individual. This speech defect was much worse when emotional, and very much less when she was calm. She had also various vaso-motor disturbances, redness, swelling, and perspiration, in various parts. With her nervous symptoms there was a complete change in her whole being, from a cheerful active woman interested in and interesting to everybody, to one who attended to and was interested in nothing, crying, despondent, her mind dwelling only on her many ailments.

The symptoms, of which only a few have been mentioned, varied much in intensity. At times they were so severe as to make life a burden to herself and her family; again, after a sojourn at the sea-shore, or in the South, she improved so much as to be comparatively well, though still far from being her old self. Her health was thought to be the best it had been since she first took sick, just before the occurrence of her last and fatal malady.

About January 6 or 8, 1894, she began to complain of pain in the right arm. A few days subsequently she said to her physician: "You see my arm is paralyzed." On examining her he found that she could move the arm freely. He saw no evidence of paralysis, and tried, in vain, to convince her of this fact. But it was soon observed that she could not move the right hand, and in a day or two the right elbow, and after an interval of a day or more, the right shoulder also became affected.

I saw her January 14th. She walked with difficulty, leaning upon an attendant for support, but the strength of the different groups of muscles of the legs appeared to be good, a rough test indicating that the muscles of the right leg equalled in strength those of the left. The right hand was altogether powerless, and there was but little strength in the muscles of the right elbow and shoulder. She felt a light touch everywhere on the right arm and leg, but on the arm the touch was not quite so well localized as on the left arm. Tendon reflexes normal, cranial nerves, fundi oculi normal, no headache.

The patient was in an hysterical emotional state, cried and laughed alternately, the feelings appearing to be very superficial. On account of either mental confusion, or inattention, or impaired speech, there was little satisfaction to be obtained from her statements. She spoke little spontaneously, often seemed not to grasp the meaning of a question, or paid no heed to it. When she spoke it was in a faltering manner, seeming to have difficulty in finding and arranging her words. This mental state did not appear to be a new feature. Like conditions had frequently been observed in bad periods in former years. But the apparent mental confusion was greater; this and the appearance of a new symptom, paralysis, was all that distinguished her condition now from what was often observed in her before.

I saw her again January 17th. Her mind was more blunted. She scarcely spoke any, and paid little heed to questions, so that the examination of subjective states was not satisfactory. She was now confined to her bed. She apparently could not move the right arm at all. She could move the lower extremities freely, though the degree of strength could not be tested. The prick of a pin was felt everywhere.

After my second visit an examination of the field of vision was made by an oculist. By an oversight this had not been made sooner. He found concentric contraction of the field of vision of each eye. I shall give my reasons further on for believing this observation was not accurate.

The chief change in the following ten days was a constantly increasing mental apathy, and disinclination to speak or to move, and that she ate less and less. The paralyzed arm was somewhat rigid much of the time, so that there was some resistance to passive movements. The latter were often painful. The pulse was strong, in the neighborhood of 80, temperature mostly normal.

February 1st.—Strong faradic brush applied to right arm and leg very painful, in leg produced a movement, a flexing at the same time of hip, knee, and ankle, but the arm remained motionless. Temperature in left axilla, 98°, in right, 99.8° F. Can scarcely get any response from patient except an occasional "Yes" and "No."

February 3d.—Cathartic given, and bed soiled, of which she is altogether regardless. Eats very little, hebetude extreme, temperature 98.5° F. in each axilla.

February 4th.—Did not speak a single word. Lies almost motionless, takes scarcely any food.

February 5th.—I found her in the morning in a comatose condition, breathing heavily, face somewhat flushed, pulse 90, temperature 103.1° F. in each axilla. A very slight movement of the left arm and leg could be produced by deep pricking, right extremities motionless and flaccid. Breathing regular. Some puffing of the lips with each respiration, but lips close in swallowing (swallowed a little fluid). When eyelids lifted, eyes were seen to move restlessly to and fro.

During the day the temperature subsided somewhat and her condition appeared a little better. There had been a deep burn on right leg a week before through an accident with a hot brick. Pressure in this to day caused a movement of right leg with other manifestations of pain.

On subsequent days there were slight fluctuations in her condition, temperature varied from 99 to 102.5.° F., usually one to one and one-half degree higher on the right than on the left side; pulse remained good, until the last day or two of life when it became rapid and feeble. She swallowed liquid food without much difficulty. She was sometimes in apparently sound sleep, and at times even manifested a certain degree of consciousness, opening her eyes, moaning "Oh, my;" and the nurse thought that she distinguished between food and bad-tasting medicine. The breathing had at times something of the Cheyne-Stokes character, at other times it was heavy, labored, attended by paralytic puffing of the lips and cheek, again there were intermissions of quiet healthy breathing.

February 7th.—It was first observed on this date that the tendon reflexes in right arm were heightened, and they remained so until the end. In the right leg the tendon reflexes were at no time excessive. There was no subsequent movement of left leg, excepting not infrequently a kind of tremor or clonic spasm. On some occasions the left hand was found in a state of contracture. During the last few days of life, the only evidence that a pin prick was at all felt was that it sometimes was followed by a movement of the left leg. There was at no time true facial paralysis.

During the last week of life there was a tendency to keep the face turned toward the right. If the head were straightened she manifested pain. She died February 12th.

Only the contents of the cranial cavity were examined *post-mortem*. There was a lepto-meningitis of light grade confined to the pia covering the convexity of the hemispheres, and most marked over the softened areas. The beginning of the right middle cerebral artery appeared narrowed and thickened, but the vessel beyond was patulous, and not collapsed. Otherwise the vessels at the base were normal.

Three areas of softening were found on the surface of the hemispheres. The largest and, probably, oldest was in the left motor area. It destroyed almost the entire upper two-thirds or three-fourths of the central convolutions, and a small part of the contiguous frontal and parietal lobes. The softening extended deeply into the centrum ovale, but did not reach the lateral ventricle. The paracentral lobule was unaffected.

The second area of softening was in the right occipital lobe. Almost the entire lobe was affected, the softening reaching to the posterior and inferior horns of the lateral ventricle. The third and smallest, and, perhaps, most recent softening, was in the posterior part of the second frontal convolution. The lesion just impinged upon the ascending frontal convolution. The softening extended about one-fourth of an inch into the white matter.

The other parts of the brain, as far as could be judged by naked eye appearances, were altogether normal.

Remarks.—The case illustrates the difficulties and uncertainty in the diagnosis of hysterical paralysis; also that the presence of hysterical conditions—upon which the diagnosis, hysterical paralysis, must always chiefly rely—does not preclude the existence of organic disease. This was regarded as a case of hysterical hemiplegia, until its gravity revealed the presence of organic disease.

The features of the case which lent it its hysterical aspect were the following:

1. A history of repeated hysterical manifestations, and the recurrence in the last illness of similar manifestations. Furthermore, the paralysis was preceded by pain in the arm—pain often excites hysterical paralysis—and by the fixed idea that she was paralyzed. 2. The hemiplegia had peculiar features, ordinarily characteristic of hysterical hemiplegia. There was no facial paralysis, which is invariably true of hysterical hemiplegia. When the diagnosis hysteria was made the paralysis was not complete; and this is also the rule in hysterical hemiplegia. The paralysis came on very gradually. This is not uncommon in hysteria, whereas it is exceedingly rare as the result of a brain lesion, excepting in cases of tumor, abscess, sclerosis, or chronic softening, all of which could be excluded in this case.

Finally, the visual symptom, concentric contraction of the field of vision in each eye, is most frequently found in hysterical cases. But my impression is that this was a mistaken observation. The autopsy revealed a softening of the right occipital lobe, which would cause the loss of the left half of the field of vision in each eye. It is true we do not know that this lesion was already present when this examination was made; but inasmuch as at the time of the examination the mental condition of the patient prevented a careful and perhaps accurate examination, and the vision was tested for the very purpose of finding out whether the field was contracted or not, it is not improbable that the loss of one-half of the field was confounded with a contracted field of vision.

There were some respects in which this case did not correspond to the most common picture of hysterical hemiplegia. The paralysis was right-sided, the arm was more affected than the leg, and there was no anæsthesia; whereas in hysterical hemiplegia the left side is usually affected, the leg more than the arm, and there is often more decided loss of sensation than of power. But these differences are too common to have much weight in diagnosis.

This, then, is one of those not uncommon cases where an hysterical subject, with hysterical symptoms, has organic disease. The peculiarity of this case was that, while the patient's history led to the expectation of new hysterical manifestations, the new symptom in this instance, the hemiplegia, had in itself so much that is commonly characteristic of hysteria.

The most striking feature of this case is the gradual onset of symptoms. From the very beginning there was a steady progress of the symptoms, from day to day, almost to the very end. This was true of the motor paralysis and the mental impairment. This is not the mode of onset and course in cases of acute softening. Wernicke describes a very rare disease, which he terms chronic softening of the brain, wherein there is a very slow and gradual increase of motor and sensory paralysis, which may continue for months or even a few years, a disease which Wernicke believes to be of an inflammatory character. But acute softening, which is due to the occlusion of blood-vessels, usually produces symptoms which are more or less sudden in onset. When the cause is embolism the symptoms are always ushered in abruptly; and this is, also, largely true in cases of thrombosis. Even in cases of senile softening of the brain, where the slow appearance of symptoms is most likely to be found, the latter mostly occurs as a series of slight attacks. In Dr. Diller's case, which belongs to this order and where the gradual onset was uncommonly well marked, the phenomena are explained by the unusual pathological condition found. But my own case was not one of senile softening, and I do not know of another of its kind in which occurred such a gradual development of paralysis.

In part the latter was due to the multiple lesions, which doubtless occurred one after another. Very likely the lesion in the left central convolutions appeared first, then that in the right occipital lobe, and finally the area

of softening in the right frontal lobe. The latter probably accounts for the attack of coma which came on a week before death, and for the loss of power in the left extremities, though the lesion only slightly encroached upon the motor area. That there was no facial paralysis is explained by the location of the lesion in the motor area.

SPLENECTOMY, WITH THE REPORT OF A SUCCESSFUL CASE.[1]

By W. J. CONKLIN, A.M., M.D.,
DAYTON, O.

Mrs. A——, American, aged twenty-nine, married, II-para, was admitted into St. Elizabeth Hospital, May 29, 1893. The following history was obtained. Her family record is without taint, menstruation normal, and general health but little impaired. Mrs. A.'s early life was passed in a highly malarious district in Southern Illinois, and up to her marriage and removal to Ohio she was subject to frequent attacks of chills and fever, and carried almost constantly an "ague cake" in her side. For several years she has been free from malaria and, aside from an attack of typhoid fever, has had no serious acute illness.

The symptoms of the disorder which now so seriously interferes with the discharge of her household duties, and for which she seeks relief, first showed themselves about two years ago. She then began to have abdominal and pelvic pains, and some months later discovered a lump low in the abdomen. Examination disclosed a solid, freely movable tumor, sensitive to touch, in the left iliac region, dipping into the pelvis, but not connected with the uterus, and a small cyst of the right ovary. The uterus was normal in size, but retroverted.

Dr. Jewett, during whose service she entered the hospital, made a cœliotomy, June 10, 1893. The solid tumor proved to be a displaced spleen about twice the normal size. It was free from adhesions and easily replaced. The right ovary, containing a cyst the size of a small orange, was removed. Left ovary normal. The abdomen was closed without drainage. Convalescence was uneventful. She was soon discharged with positive instructions to wear constantly a properly fitting abdominal supporter, with the hope of retaining the spleen in position.

Mrs. A—— was readmitted into the hospital during my service, September 23, 1893. Shortly after her return home she again began to suffer from pelvic symptoms, and for the past two months has had nearly continuous abdominal soreness and several severe paroxysms of pain, which drove her to bed. Her abdomen has been steadily enlarging.

Six days ago, while doing the family washing, she was seized with agonizing pain in the abdomen, which required for its control the administration of morphia. Vomiting of large quantities of bile-colored fluid began on the following morning, and still recurs at intervals. In spite of treatment the bowels have not been opened for more than a week. Temperature normal.

On examination, the abdomen was found tympanitic, very sensitive to pressure, and occupied by an immovable, solid tumor which completely filled the left side from the pelvis to the ribs, and extended considerably beyond the middle line. It could easily be touched *per vaginam*.

The former operation greatly simplified the diagnosis, and left no doubt that the tumor was the enlarged and inflamed spleen. The acute symptoms were attributed to intestinal obstruction, due either to pressure from the spleen or to adhesions at the seat of the ovarian stump. The symptoms grew steadily worse until forty-eight hours after admission, when the bowels responded freely to treatment, after which the vomiting ceased and her general condition improved. The respite was of short duration. The local tenderness, paroxysmal pains, and vomiting returned accompanied by fever. The temperature ranged from 99° to 101° for ten days, and measured 100° on the morning of the operation. Peritonitis had evidently supervened, and at a consultation of the hospital staff it was decided that the removal of the offending spleen offered the only chance of recovery.

The operation was made October 7th, with the assistance of Drs. Jewett and Humphreys, the patient having been anæsthetized by Dr. Reeve, Jr. The parietal incision, seven and a half inches in length, was made along the outer border of the left rectus. On exploring the spleen, contrary to expectations based on the revelations of the previous operation, it was found adherent to the abdominal wall, omentum, and intestines. The intestinal adhesions especially were firm and extensive, involving the entire under and inner surfaces of the tumor. Their separation consumed much time, and with the utmost care the capsule of the spleen was torn in several places. The peritoneum gave unmistakable evidences of active inflammation. The pedicle was long, twisted through three complete turns, and with its engorged and tortuous vessels resembled a huge umbilical cord. It was transfixed, firmly tied with heavy twisted silk, using the Staffordshire knot, and for greater security encircled with another turn of the ligature. The ligature was cut short and the pedicle dropped, a glass drainage-tube placed, and the wound, on account of the patient's condition, hastily closed.

The hemorrhage was slight and easily controlled. The shock, however, was profound and wholly out of proportion to the blood lost or the length of the operation. Hypodermatic injections of brandy and strychnia were freely used. Apart from the shock which threatened to prove fatal for hours after removal to bed, and the temperature which for twelve days measured from 99° to 101,° precisely as it had before the operation, there was nothing worthy of special comment during convalescence. No satisfactory explanation of the temperature curve could be found in the condition of the wound or patient, and indeed, without the thermometer it would not have been suspected. At no time was there swelling of the parotid or lymphatic glands. The spleen drained of its blood weighed four and a quarter pounds, and measured ten inches in length by five and a half inches in breadth. It was firmer in texture and darker in color than the normal gland. Microscopical examination, by Dr. Scheibenzuber, showed thickening of the trabecular and intercellular connective tissue and pigment in the vessel walls, "a chronic hyperplasia probably due to malaria." By an unfortunate oversight, no microscopical examination of the patient's blood was made before or soon after the operation; at present the proportion of the red and white corpuscles is normal. Seven months after the extirpation, the date of the present report, Mrs. A——, has grown very fleshy and reports that she is in excellent health save in one particular—an overpowering drowsiness. When quiet, it requires constant effort to keep awake. The habit seems to be increasing and is a continual source of annoyance and embarrassment.

It is not our intention to enter into a detailed discussion of the surgery of the spleen, but propose simply to supplement the above report with a few general comments.

Although practically a modern operation, splenectomy has a history which runs far back into the centuries.

Dionis (1733), quoted by Greig Smith, speaks condemningly of a sect of surgeons who achieved notoriety, about the close of the seventeenth century, from their operations of "unmilting," as removal of the spleen or milt was termed. The only successful total extirpations for disease recorded previous to 1867 were those of Zaccarelli (1549) and Ferrerius (1711), both of which have been discredited, probably erroneously, by many authors. In nearly all of the statistical tables, Dr. G. Volney Dorsey, formerly a distinguished member of this society and an accomplished scholar and surgeon, is credited with a successful splenectomy made in 1855. Ledderhose

[1] Read before the Ohio State Medical Society, May 17, 1894.

refers to this case as the first authenticated successful laparo-splenectomy on record. A reference to the original publication,[1] for which I am indebted to Dr. Billings, United States Army Medical Library, shows that Dr. Dorsey, in this very creditable pioneer effort in splenic surgery, did not remove the spleen, nor is there any evidence that he ever entertained such a proposition. The operation was undertaken for the relief of pain in an enlarged spleen of malarial origin. On opening the abdomen extensive adhesions were found and treated as the source of trouble. "I then proceeded," says the operator, "to break up all of the adhesions of the spleen, and endeavored to place this viscus as nearly as possible in what I conceived to be its natural position." The introduction of splenectomy into modern surgery dates from the memorable case of Péan, who in 1867 successfully removed from a young woman an enlarged and cystic spleen. Since then the operation has not only been accorded a place in legitimate surgery, but has been extensively practised with fair success, though the mortality-rate is still higher than in laparotomy for any other cause.

The indications for splenectomy have not been definitely settled. Taking as a basis the tables of Drs. Fussell,[2] Ledderhose,[3] and Zuccarelli,[4] and making the proper additions and corrections, we have the following summary, which fairly represents the conditions for which the operation has been made and the results attained up to date.

	Number.	Deaths.	Recoveries.	Percentage of mortality.
Hypertrophy, simple: malarial	48	28	20	58⅓
Leucæmia	27	26	1	
Pseudo-leucæmia	2	1	1	
Traumatism, no serious lesion of spleen	26	1	25	
Traumatism, rupture of spleen	6	5	1	
Floating spleen	25	1	24	
Cysts of spleen, simple: hydatid	6	1	5	
Abscess of spleen	4	3	1	
Sarcoma of spleen	3	1	2	
Syphilis of spleen	1	0	1	
Amyloid disease of spleen	1	1	0	
Healthy spleen	1	0	1	
Total	130	78	82	45⅓

Like all statistical tables promiscuously gleaned from current literature, this one must be taken *cum grano salis*, since it is always a fair presumption that fatal cases are less likely than successful ones to find their way into print.

The celebrated case of Franzolini (1881), which however has not gone unchallenged, still remains the only successful splenectomy for leucæmia. With the exception of Bardenheuer's case, which died from sepsis on the thirteenth day, none survived the operation longer than a few hours. Hemorrhage and shock were the cause of death in all but three cases.

There are a few writers (Fulsell, Adlemann, Asch) who, in view of the hopelessness of medical treatment, still look with favor upon surgical procedures, provided the operation is made when the gland is only moderately enlarged and before profound alterations have taken place in the blood. The consensus of opinion is, however, strongly opposed to this view.

The insidiousness of the onset of leucocythæmia and the extensive mutilation which splenectomy implies, taken in connection with the impossibility of eradicating the constitutional cachexia which is back of the splenic enlargement, will certainly tend to confine "early operation" within narrow limits. So far, the ghastly record leaves unimpeached the dictum of Bryant, "that the operation is physiologically unsafe and surgically unsound."

The results in simple or non-leucæmic hypertrophy are more encouraging, although the mortality-rate is still high, about 58⅓ per cent.

Agnew (1889) holds that all cases of hypertrophy, simple, malarial, or leucæmic, are excluded from the realm of operative surgery. The latest text-book on surgery takes the more conservative position that, although hypertrophied spleens have been successfully removed these cases are for the most part not suitable for operation.

These statements are hardly sustained by the facts. It is undoubtedly true that simple hypertrophy will rarely in itself be a sufficient justification for the performance of splenectomy; but in the presence of pressure symptoms, twisted pedicle leading to degenerative changes or disabling pain, all of which may be caused by a moderate enlargement of the gland, the operation is not only justifiable, but offers a reasonable probability of a favorable issue.

It is very apparent that the results are better in the later than in the earlier operations, due, probably, to a more thorough asepsis and an improved technique, and lead to the hope of better things yet to come.

The record of the past decade in the operations for simple—including malarial—hypertrophy, shows twenty recoveries and eight deaths, a mortality of only 28¾ per cent. against 58⅓ per cent. calculated upon the total operations.

In discussing this phase of the subject it is proper to take into consideration the brilliant results of extirpation for floating or displaced spleens.

In over fifty per cent. of these histories it is specifically stated that the spleen was enlarged, while in very few it is designated as normal in size. In many of the cases, as in our own, the hypertrophy was extreme and gave rise to doubts as to their correct classification.

It is difficult to estimate from the imperfect data at hand the influence of malaria in causing the enlargement which led to the adoption of operative measures. It is only given as a cause of the hypertrophy in nineteen cases, of which five died and fourteen recovered. The condition of the blood, however, is a far more important factor in determining the issue in a given case than the amount or the nature of the hypertrophy (non-leucæmic). In any proposed excision of the spleen the blood should be subjected to a careful microscopical examination, and if the relations of the corpuscles are seriously disturbed, especially if the lymphatic glands are involved, operative procedures should not be undertaken.

Splenectomy for certain traumatisms of the spleen has a much better record than for disease. The results as displayed in the table, which includes both total and partial excisions, are very remarkable, and especially when the fact is recalled that almost all of the cases which enter into it antedate the dawn of aseptic surgery.

It is, however, worthy of more than passing mention, that in the recent literature of the subject there are recorded so few removals of the spleen for traumatic causes, and none for the peculiar traumatism with protrusion which gives the extraordinary results tabulated above. But unless interpreted in the light of the case histories, these figures would be manifestly misleading. The reports, so far as they are accessible, show that the above results were obtained when there was protrusion of the spleen through or into a parietal wound without serious injury to the gland itself or other viscera.

The graver injuries included under the head of traumatic rupture have necessarily a high mortality. It is fair to assume, from the deep-seated and protected location of the spleen, that when it has received an injury severe enough to suggest splenectomy the concomitant lesions would be profound and probably fatal.

So far as we are able to ascertain, the case of Riegner[1] (1892) is thus far the only successful extirpation for a subcutaneous trauma of the spleen.

The intense surgical interest of this unique case

[1] Berliner klinische Wochenschrift, February, 1893.

prompts us to give a brief résumé. A lad, aged fourteen, fell from the third story of a house and struck on his belly. Twelve hours after the accident, signs of internal hemorrhage supervening, the abdomen was opened in the middle line; the incision was subsequently enlarged by right and left cross-cuts. The spleen was found completely torn across at its middle, and the two sections widely separated. The spleen was removed, the abdominal cavity cleansed of large quantities of clotted blood, and the patient put to bed much exhausted. Convalescence was interrupted by gangrene of the foot and leg, which a few weeks later necessitated amputation through the left thigh. He recovered from both operations, and seven months later was in excellent health.

Ledderhose investigated the comparative merits of resection, extirpation, and reposition of the protruding spleen, with the following result: Ten resections with ten recoveries; eighteen extirpations with eighteen recoveries, and four repositions with one recovery.

The conclusion seems irresistible that in prolapse of the spleen through an abdominal wound, extirpation, either partial or total, is a safer procedure than simple replacement. However, this deduction is less startling when we reflect that there is far less danger from sepsis and hemorrhage in a laparotomy, with its careful toilet of the peritoneum and better control of bleeding, than in blindly replacing the protruding organ. These statistics, contrary to the traditions of the text-books, warrant the statement that removal of the spleen is not in itself a highly dangerous operation. An opinion which is fortified by the brilliant results in the removal of floating spleens, already noticed, as well as by the fortunate ending of the case of Trendelenburg, in which he removed a healthy spleen in dissecting out a retro-peritoneal sarcoma.

Hemorrhage and shock constitute the great dangers in splenectomy, about seventy per cent. of the deaths being attributed to these accidents. Sepsis is largely eliminated by the promptness with which the fatal issue follows the operation. According to Mosler, the hemorrhagic diathesis so constantly associated with splenic enlargements, both simple and leucæmic, is often latent and therefore unsuspected before operative measures are begun. The pedicle is the most common seat of fatal hemorrhage; not infrequently it comes from the torn adhesions, and in a few cases has been attributed to a capillary oozing from the congested viscera. For greater security, some operators advise the separate ligation of the vessels of the pedicle in addition to the ordinary encircling ligature, but Treves states that no advantage has been shown to attend this practice.

The shock is often profound and, as in the case herein reported, is not easily explained. Traction upon the pedicle in manipulating the tumor has often brought on dangerous collapse, due probably to pressure upon the splenic nerve-plexus. It is not improbable that many deaths credited to post-operative collapse are really the result of a slow intra-abdominal bleeding.

The present position of splenectomy may be briefly epitomized as follows: It is unjustifiable in leucocythæmia or other conditions in which there is extensive involvement of the lymphatic glands, or a notable increase in the white blood-corpuscles.

It is indicated in tumors, simple hypertrophies, and other splenic enlargements which have proven rebellious to simpler measures and are attended with danger or serious disability.

In movable or displaced spleens requiring interference extirpation is preferable to operative fixation.

Severe traumatisms of the spleen, with or without an external wound, or simple prolapse of the gland into a parietal wound, demand, as a rule, immediate extirpation. In cases of protrusion experience shows that excision, partial or total, is a safer procedure than mere replacement.

Removal of the spleen for cystic disease has an excellent record, but most authors advise a preliminary trial of incision with drainage. In abscess it is better, except in rare cases, to incise and drain than to attempt removal of the organ.

THE DANGERS OF GLYCERINE INJECTIONS INTO THE UTERUS, FOR THE PURPOSE OF INDUCING PREMATURE LABOR.

By OSCAR EMBDEN, M.D.,

BROOKLYN, N. Y.

T. Pfannenstiel publishes in the *Centralblatt für Gynæcologie*, No. 4, 1894, an article concerning the dangers connected with intra-uterine injections of glycerine for the purpose of inducing premature labor—a method of late frequently used in this country—and gives the history of two cases treated by him with the new method, in the Gynecological Clinic of Breslau.

As I have had the opportunity to observe one case with a very similar history, showing evidently the dangers of these injections, I take the liberty to give in the following an extract of the above article together with my case and some observations of my own. I consider myself the more justified in so doing, as Pfannenstiel's first case is not free from objections, leaving only one of his cases indisputable.

In the beginning of his article the author states that injections of different liquids into the uterus (for instance the injection of tar-water: Cohen's method) have been frequently recommended, but generally very soon rejected by the profession, on account of the dangers connected with these methods. Most of them, especially Cohen's mode of procedure, are said to have one great advantage; that is prompt and sure action even in cases where the ordinary methods have failed to act.

Following this idea, Pelzer recommended the injection of glycerine between the uterus and the fœtal sac, two years ago, publishing four cases treated by him successfully in this manner. Since that time we have read very favorable reports of the new method, written by different distinguished authors, none of whom mentions any dangers connected with this treatment.

Pfannenstiel tries to demonstrate these dangers with the following two cases:

Case I.—Primipara, twenty-two years of age, enters the Clinic on September 5, 1892, in the ninth month of her pregnancy, suffering from a very bad nephritis. Her legs and face were œdematous, she has no appetite, has headache and feels very weak. In the past seven days she suffered from dyspnœa. She is anæmic, badly nourished; has a hyposcoliosis, but no narrowness of the pelvis; cyanosis in a slight degree. Respiration, 44; temperature, 97.7° F.; pulse, 130 to 166, small. The urine contains eight per cent. albumin (Esbach's method), many casts and epithelial cells, no red blood-corpuscles, a few white ones; quantity 200 c.c in twenty four hours.

September 7th, 6 P.M.—Injection of 80 c.c. chemically pure glycerine between the uterus and the fœtal sac with every possible precaution. The patient stood the little operation very badly on account of orthopnœa. She had a slight collapse before the injection and a second one immediately after it, so that she required stimulants. Soon after the injection, it was evident that it had been performed too late. The breathing became more and more difficult, the pulse became weaker. Temperature, 95.9° F. She never had a single pain. She died September 8th, at 2 A.M.

The post-mortem examination showed that she had died of nephritis. Omitting the full report of this examination, I only mention that there was one tablespoonful of blood-colored urine in the bladder. The vesical membrane was of a red color. The fœtal sac was separated from the uterus over an area of about three inches square. No glycerine was noticeable at this point.

Case II.—This is a III. para with a narrow pelvis; artificial labor four weeks before term. Pfannenstiel first

tried, without success, Krause's method for some days: he pushed in three bougies between the uterus and the fœtal sac.

September 26th, 5 P.M.—Injection of 100 c.c. concentrated glycerine. The patient had immediately after the injection very strong and very painful contractions. These subsided after some time, the uterus remaining exceedingly sensitive. There was not any effect on the cervix. One hour after the injection the woman became drowsy and cyanotic, the temperature rose to 102.2° F., the pulse became slower, 68 per minute. On the previous days it ranged between 84 and 92. This condition continued for three hours. Then the temperature became normal, the pulse a little more frequent. After that the temperature remained normal. The urine, drawn off with the catheter, one hour after the injection, quantity 1 oz., was of a blood-red color. The woman was catheterized every two hours: the urine remaining as in the beginning until ten hours after the injection, when the color began to become lighter and twenty-four hours afterward it was normal. The urine contained large quantities of albumin until forty-eight hours after the injection; it contained nearly no morphotic elements, except some particles of hyaline casts, no red blood-corpuscles. The spectrum-analysis showed that there was methæmoglobin and hæmoglobin in the urine. The general feeling of the patient was not disturbed after the operation, but the appetite was poor for three days.

Premature labor was successfully brought on by means of the colpeurynter. The delivery of a living child took place September 28th, at 4.30 P.M. Puerperium without complications.

The case, observed by myself, is as follows: Primipara, aged twenty-four, in the ninth month of her pregnancy. She has had albumin in the urine for three weeks, the amount of which is rapidly increasing in the last few days, in spite of a very strict milk diet (seven per cent., Esbach's method). The quantity of the urine is about one quart in twenty-four hours. The sediment contains a few white blood-corpuscles, no red ones, a few renal epithelial cells, and a few hyaline casts. The patient has a headache, feels sick to her stomach, and very tired. She has slight œdema of the feet and hands. Under these circumstances it seemed best to induce premature labor as soon as possible.

March 19, 1893, 1 P.M.—Injection of 90 c.c. pure glycerine between the uterus and fœtal sac (Dr. Charles Jewett). This had to be done in chloroform narcosis, as the patient was very nervous. Soon after she recovered from the narcosis she had slight pains at longer or shorter intervals until 7 P.M. At that time the uterus was very sensitive, but there were no real contractions.

At 7.30 P.M. the patient had a very severe eclamptic convulsion of about three minutes' duration. As it was very desirable to terminate labor as soon as possible, and the cervix barely admitting the little finger, manual dilatation was very skilfully performed by Dr. Jewett, at 9 P.M., and a living child extracted with his own axio-traction forceps. The temperature was normal all the time, but the pulse-rate was very slow, ranging between 50 and 55 per minute; before the injection it was 78. The urine was not drawn off before delivery. The first urine after delivery—drawn with the catheter—was of a dark red color. It contained no red blood-corpuscles, but a large quantity of hæmoglobin. After twelve hours the water was only slightly colored, and twenty-four hours after delivery the color was normal. The albumin disappeared gradually. The next day after delivery a severe icterus set in, and the patient fell in a semi-comatose condition, which continued for six days. By this time the icterus and the coma had disappeared, and the patient recovered gradually.

In the first place, it is demonstrated by these three cases that the glycerine-injections do not act as quickly as we should expect. Pfannenstiel concedes himself that his first case is of little value in this respect, as it was too far advanced for any treatment; but his second one illustrates clearly that the injections of glycerine were of no more use than Krause's method (introduction of bougies). My case shows that there was, about seven hours after the injection, only a very slight dilatation of the cervix, although the patient had constant pains from the beginning.

Pfannenstiel is perfectly right in considering much more important than this the fact that Pelzer's method is liable to occasion indisputable symptoms of glycerine poisoning. This will be—as he says—a death blow to the method.

Concerning the first case, he does not, of course, consider the glycerine as the cause of the woman's death, but the nephritis. He deems it remarkable, nevertheless, that there was found a small quantity of blood-colored water in the bladder, the urine being entirely free from blood in the last days before the injection was performed, as shown by frequent examinations. Pfannenstiel tries to find the cause of this in the injected glycerine.

The second case was undoubtedly a case of glycerine poisoning, and although it did not damage the future health of the woman it kept her in danger for some time. The woman was in perfect health up to the time of the injection; the urine was normal. One hour afterward she had the symptoms above mentioned.

In my case there is a woman with nephritis, but there was not noticed at any time before the injection any trace of blood in the urine. After the delivery there was a good quantity of a dark red urine in the bladder. In examining the same, I failed to find any red blood corpuscles, but there was a large amount of hæmoglobin. Therefore the cause of this could not have been an acute congestion of the kidneys, as we at first thought—for there was no hæmaturia, but a hæmoglobinuria—and the only explanation we could find for this was a decomposition of the blood, brought on by the injected glycerine.

This does not seem so very strange, as we know—according to Pfannenstiel—that glycerine is liable to occasion a decomposition of the blood, as Luchsinger,[1] Schwan,[2] Filehne,[3] Lébédeff,[4] and Wiener[5] have demonstrated and Afanassiew[6] has shown, experimenting with dogs and rabbits, that the hæmoglobinuria, caused by glycerine, brings on a glomerulo-nephritis which is followed, after the injection of more glycerine, by interstitial nephritis as well as by interstitial hepatitis.

It is, of course, strange that neither Pelzer nor others met with a similar accident after injections of glycerine.

Pfannenstiel finds an explanation of this in the fact that Schwan, Lébédeff, and Filehne have shown that in rabbits, when the glycerine is brought under the skin, hæmoglobinuria always occurred, but that it did not occur, or in a slight degree only, when it was injected directly into the veins. Without giving an explanation of this remarkable fact, Pfannenstiel deems it possible that, in Pelzer's cases, the glycerine was very rapidly absorbed by the circulatory system, while in his cases it acted in the decidua uteri as if it had been injected by the hypodermic method.

There is another thing about which I would like to say a few words, that is the icterus which, in my case, followed the hæmoglobinuria. On this account it seems to me especially interesting.

It is not very important whether this was, according to Kuehne's [7] theory, a real hæmatogenic icterus, that is, an icterus directly caused by the pigment of the decomposed red blood-corpuscles, or a so-called hæmo-hepatogenic icterus, which is said by Afanassiew, who denies the existence of a real hæmatogenic icterus, to be an indirect result of this decomposition only. This author thinks

that the pigment of the destroyed red blood corpuscles is deposited in the liver, where the gall pigment is normally formed out of the blood pigment, and the icterus occurs, in his opinion, on account of an overplus of gall-pigment in the liver, a part of which reflows into the blood.

Leaving this question undecided, one thing seems to be indisputable, and that is, the icterus was caused, in my case, either directly or indirectly by the decomposition of the blood poisoned by glycerine.

I would not dare to say that the semi-comatose condition of my patient, which disappeared with the icterus, was brought on by the same cause. It did not look like a uræmic coma, and we were unable to account for its origin. It might possibly have been one of the indirect effects of the decomposition of the blood, but it is better to leave this an open question.

Pfannenstiel also points out another danger of the injection of concentrated glycerine, and that is, according to the authors above cited, the possibility of a thrombosis, which concentrated glycerine, when brought into the circulatory system, may produce.

In addition to all these objections, there has still to be mentioned another danger connected with the new method as well as with the injection of any kind of fluid between the uterus and the fœtal sac, namely, the possibility of air entering into the circulatory system. This cannot be absolutely avoided, even with every possible precaution.

All this together seems sufficiently to show the great dangers connected with Pelzer's mode of procedure. It ought not to be used at all for the purpose of inducing premature labor, but especially not, in my opinion, in cases of nephritis, as we have seen that the glycerine is very liable, on account of its irritating effects on the kidneys, to make the existing nephritis worse.

If, in calling the attention of the profession to the dangers of Pelzer's method, I shall have convinced them that it is not a method for indiscriminate use, I will have attained my object.

Clinical Department.

AN ECHINOCOCCUS CYST SIMULATING ASCITES.

By MARCELL HARTWIG, M.D.,

Buffalo, N. Y.

D. R——, an Italian, appeared in my office February 1, 1894, saying that he had been sick about five months with loss of strength. Upon examination he presented all the symptoms of ascites, except that there was a very gradual change of the percussion dulness in changing position, and also that there was a remarkable bulging of the epigastrium. On February 5th I tapped him midway between the symphysis pubis and umbilicus. Over five quarts of an intensely green liquid were removed. A great many brown lumps and flakes came along, some with a gritty feel. The whole liquid appeared more viscid than ascitic fluid usually does. Microscopic examination showed rhombic dark brown crystals, which Dr. Benedict found to be bilirubin, fatty round-cells, and some large rings with double contour and two or three central dots which I could but consider eggs of some worm, but whether of ascaris or tænia I could not determine. The liquid was rich in bile. After the liquid was removed nothing unusual could be felt in the abdomen. The temperature was 100° F. in the rectum, pulse 79. Five weeks after the tapping the patient began to feel uncomfortable again, although he had gained some in weight. Jaundice had not existed previously, nor did such appear after the tapping. Fluctuation was distinct again and I was almost ready to push the trocar through the old place, when it became evident that the liquid was above that point, and that, in standing, the lowermost parts of the abdomen gave a tympanitic sound up to the middle point between the symphysis pubis and umbilicus. So, after an exploratory puncture with a hypodermic needle a finger's width above the navel, I pushed a good-sized trocar in and emptied what I now believed to be a sac. There were about two and one-half quarts of liquid with the former characters, only that the search for eggs proved futile. Through the cannula a Nélaton catheter, previously fitted, was introduced to the depth of a foot, and over it the cannula withdrawn in order to establish permanent drainage. Liquid of the same character kept oozing from the end of the catheter. While I was contemplating how to produce adhesive inflammation—thinking, for example, of injecting tincture of iodine, as in hydrocele, but fearing poisoning—natural infection came to my aid. The patient became feverish, the temperature often rising to 103° F.; the liquid began to turn into pus containing streptococci only. After a week's fever I thought the reaction plenty strong enough, and began injections of peroxide of hydrogen, which brought out some crystals for a while. The size of the cavity began diminishing. April 17th it admitted only 850 c.c. April 25th, 150 c.c.; May 3d, 100 c.c.—at a pressure of twelve to fourteen inches of water.

The patient was up and around again. May 17th liquid oozes immediately next to the catheter. I shall shorten the latter daily, as there is no doubt the process is at an end and the cavity gone. What else than an echinococcus cyst communicating with the gall-bladder or probably with a bile duct in the liver could this case represent? That the gall-bladder did not communicate with the cyst seems to me probable, from the fact that a probe introduced into the channel of the catheter, after the latter's withdrawal, seemed to reach decidedly too far underneath the lower surface of the liver, and that the stools were of natural color. This is the first case of echinococcus I have seen in fifteen years in Buffalo, although I have watched for it. The patient, liquid, and slides were presented in the Buffalo Academy of Medicine; and, during the discussion, a gentleman expressed his fear that such a method of drainage might expose the patient to leakage of fluid into the peritoneal cavity with resulting peritonitis. But the danger seems to me absent, even if the cyst should retract off from the abdominal wall, as long as it is emptied well so that there is no internal pressure left. In a few days a channel is formed of inter-intestinal adhesions, forming a perfect pipe, cutting off the general peritoneal cavity. Such a condition I saw years ago, when I placed a thorough drain from an abdominal incision through Douglas's pouch. Nothing would drain after a few days, until after about fourteen days an abscess in the neighborhood emptied itself into the channel, which was purposely kept patulous by the drain. The first few days the catheter, properly fitting the trocar cannula, will remain fluid-tight in the cyst as long as there is no internal pressure; afterward the adhesions suffice, if the cyst is ever so far retracted.

Reynier's[1] case of peritonitis after puncture of an echinococcus, where he warns, seems to me not good comparison, as, at least from the report, it seems that the cyst was not entirely emptied and the drainage not maintained. There is no doubt to my mind that the simplicity of this proceeding is far preferable to incision *à deux temps* (Volkmann) or to stitching the cyst to the abdominal wall and incising. The only difficult point is to determine where the probable root of the cyst is. This is important, in order to insert the trocar in its close neighborhood, so that the drain channel should not be too long. May be that even unilocular ovarian cysts could be thus cured. Impossible it does not seem to me even for multilocular cysts, although the present *modus operandi* is simpler for the latter. The future undoubtedly will show a great extension of this procedure.

Another argument supporting my view of the nature of

[1] Year-book of Treatment, Lea Brothers & Co., 1894.

this case is Weichselmann's observation that the connective tissue wall of echinococcus cysts contains bile-ducts which readily open into the cyst if the wall of the latter begins exfoliating. Thus it was frequently seen that echinococcus cysts began oozing bile after having been draining for some while. Here this occurrence happened only before the operation. The amounts of bile oozing were seen as high as one litre *pro die*, and it is no wonder that the whole contents of our cyst seemed to have been bile.

I have recently shown my patient a specimen of tapeworm, and asked whether his dog in Italy three years ago used to pass similar pieces; and he said the dog did, while he wondered about it. Usually there were only two or three pieces.

A CASE OF TRANSPOSITION OF THE VISCERA.

By HENRY J. HERRICK, A.M., M.D.,
CLEVELAND, O.

It occurs to me that the readers of the MEDICAL RECORD might be interested in hearing of a rather unique case, at present in Lakeside Hospital, Cleveland, in which the positions of the internal viscera seem rather mixed.

John S——, a German laborer, twenty-five years of age, entered the hospital about three weeks ago complaining of loss of appetite, weight, and strength. He had eight brothers and sisters, all of whom died while young, and he has always been delicate himself, and unable when a boy to knock around as his fellows did.

Upon examination, this unusual state of affairs was found: His heart is normal in size and correct in position, except that it is on the right side. The apex beat is in the fifth intercostal space, and one inch from the nipple, toward the median line; his liver is normal and in perfect position, except that it is on the left side; while his stomach seems to have changed places with the liver, and is on the right side. His spleen could not be made out.

355 ERIE STREET.

REPORT OF A CASE OF ACUTE SUPRA-GLOTTIC ŒDEMA WITHOUT APPARENT CAUSE

By JOHN H. PRYOR, M.D.,
BUFFALO, N. Y.

The term œdema of the glottis is often used improperly, and the grouping of all cases of œdema of the larynx under that head leads to confusion. Œdema of the glottis, or interior of the larynx, is of relatively rare occurrence, and in most of the reported cases the morbid condition is confined to the region above the vocal cords. This is particularly true of simple œdema, and for many reasons an anatomical distinction should be made. The term supra-glottic œdema seems to answer the requirements of accuracy and clearness.

J. S——, a dentist by profession, aged thirty, vigorous and healthy, consulted me on July 15th for difficulty in speaking and breathing. He had retired as usual the previous evening, and was awakened in the early morning by a slight sense of fulness and discomfort in the region of the throat. In the morning, thinking the trouble trifling, he went to his office and began his usual work. The local trouble became more urgent, and I saw him about three o'clock. At that time there were no objective signs of difficulty in breathing. The face wore an anxious look, but the feature which immediately attracted my attention was the peculiarity of the voice. The sound was new to me. It was metallic in quality and seemed to come from a cavern. I can think of no better definition than the word sepulchral. Enunciation was distinct, and there was no difficulty in understanding each word. The character of the voice differed distinctly from the muffled quality which is usually heard in secondary œdema, and was devoid of hoarseness; an examination revealed no evidence of acute pharyngitis or rhinitis, but marked œdema of the epiglottis and aryepiglottic folds. The epiglottis showed a line of division in the centre which gave the appearance of two large puff balls. It was erect and too firm to be aspirated into the glottis; at the base or lingual surface of the right side a large bleb of about one fourth inch in diameter was plainly seen. The aryepiglottic folds were greatly distended, and infringed directly upon the surface of the epiglottis. Any view into the larynx was impossible, owing to the extent of the tumefaction. The opening for the admission of air was almost entirely obliterated. Only the narrowest chink was visible when the patient uttered a vowel sound. There was pronounced infiltration of the connective tissue of the neck in the region of the larynx. Pressure on the larynx did not produce pain, and there was no complaint of pain or soreness in the throat or larynx; simply a suffocation feeling and no general symptoms whatever. Breathing eighteen to the minute, and temperature and pulse normal. I hurried the patient home, and at four o'clock the voice became husky and later whispering. The breathing grew more rapid and labored, and the face very pale. Applied six leeches in the region of the larynx. Ordered hot mustard footbath, wrapping in blankets and copious drafts of hot lemonade and whiskey. The sweating which followed was most profuse. When the leeches dropped off the swelling of the neck had disappeared. The neck was then packed in ice and the patient sent to bed. The day was unusually warm and the degree of humidity remarkably high, consequently steam was not employed. At six o'clock the breathing was much easier and the voice could again be heard. At eight o'clock the left vocal cord could be seen and the breathing was natural. I remained near the patient to scarify, if necessary. The local improvement was so marked at midnight that I considered it safe to leave him in the care of a nurse.

Upon inspection the following morning the œdema was confined almost entirely to one side, and the same afternoon both cords could be seen. They were pinkish in hue, but showed no traces of inflammation or œdema. Whether the œdema was confined to the epiglottis and aryepiglottic folds cannot be stated, but I believe that the loss of voice was due to transitory congestion of the cords.

On Monday, forty-eight hours after the attack, the patient was well and at work. I have examined him repeatedly since and never found any evidence of local disease. He has never shown any evidences of cardiac or renal disease, and I have been unable to discover any constitutional condition which might account for the strange attack. The usual causative factors were absent, and after searching the literature no clew as to the direct cause can be furnished. No similar case has been reported, to my knowledge. Some of the authors consider phlegmonous laryngitis and œdema of the glottis as practically the same affection. That there is a decided difference in the two conditions cannot admit of doubt, and this reported case of simple œdema emphasizes the fact. Cases of a somewhat similar nature have been recorded, which owed their origin to exposure, cold, untoward drug action, etc. —elements absent in my case. The possibility of it belonging to the angio-neurotic variety of œdema described by Quinéke and others, calls for comment. The cases reported by Quinéke, Dinkebarger, Strüburg, Osler, and others were essentially different in history and symptomatology. They were mostly characterized by recurrent attacks, skin eruptions, digestive disturbances, and a history of heredity. Careful inquiry and extended observation only prove the absence of all the accompanying features which make the so-called neurotic œdema diagnostic. This condition is at present obscure, and we are not in a position to decide what should or should not be included under this term.

The evanescent character of the attack might lead one to explain the anatomical changes by ascribing the condi-

tion to vasomotor disturbance, or temporary stoppage of the lymph-channels. The former seems most reasonable, although unaccountable, and the latter theory gains support by the knowledge of the distribution of the lymphatics which Hajek has supplied.

A more extended consideration of the possible causation might be interesting, but I prefer to present the case at this time as rare and most puzzling, and to state briefly the following points of clinical value: 1. The absence of any known causative agency and constitutional symptoms. 2. The extent of œdema, which may occur without marked dyspnœa. 3. The peculiar character of the voice. 4. The marked benefit of prompt treatment without scarification. 5. The possibility of the case belonging to a group of obscure clinical manifestations known as angio-neurotic œdema or allied vasomotor curiosities.

A CASE OF PNEUMONIA IN AN INFANT FIVE MONTHS OLD TREATED WITH INHALATIONS OF OXYGEN.

By RICHARD P. FRANCIS, M.D.,
SURGEON TO MOUNTAINSIDE HOSPITAL, MONTCLAIR, N. J.

The following case seems worthy of record because of the immediate and very gratifying result that followed the use of oxygen when the patient was in an apparently hopeless condition. Oxygen has often been used in treating pneumonia in adults and children, but it is believed that its use with infants is not so common, and it is hoped that this account may be of service to anyone who may encounter a similar case.

The patient was a bottle-fed baby, five months old, well developed and nourished, and of healthy parentage; she had always been well up to the time of the present illness. On March 1, 1894, after having had a cough for two or three days, she was taken with a chill. Physical examination soon after showed a few fine râles in the right upper back, but no dulness and no bronchial breathing. Temperature, 102.8° F.; pulse, 180; respiration, 45. On March 3d, bronchial breathing developed and the respirations reached 100 per minute, while the pulse was 180 and the temperature 105° F. Ten drops of brandy were given every half hour, and a cough mixture of muriate of ammonia, fluid extract of licorice, and whiskey every two hours. The next day the circulation was very bad, the extremities became cold several times, and the face dusky. At 5 P.M. the child was put in a hot mustard bath and there were given twenty drops of brandy in which was dissolved a tablet triturate containing one minim each of tincture of digitalis and tincture of strophanthus, one-eighth of a minim of tincture of belladonna, and one two-hundredth of a grain of nitro glycerine. A good reaction soon followed. From this time on the "heart stimulant" tablets were given every three hours. Their effect on the heart's action was most marked; not so much in diminishing its rapidity as in increasing its force.

For the next five days the case ran a fairly typical course—the pulse averaging 160 and the respirations 120. It is interesting to note that on four occasions the respirations were more rapid than the pulse. On March 4th, at 12 M., respiration, 140; pulse, 130. March 5th, at 8 A.M., respiration, 120; pulse, 100. March 6th, at 4 P.M., respiration, 144; pulse 140. March 7th, at 4 P.M., respiration, 130; pulse, 120. The treatment was taken well, and two or three ounces of Pasteurized milk were given daily. Special care taken that the child had plenty of water, which she took eagerly and with evident gratification. Frequently brandy was administered in twenty-drop doses for four or five consecutive hours, to stimulate the flagging heart. On the morning of March 11th the record of the temperature, pulse, and respiration showed them to be the lowest since the beginning of the attack, and an examination of the chest gave evidence of beginning resolution. The next day the temperature was elevated, as were the pulse and respirations, and on the 13th bronchial breathing was found in the left upper back.

The pulse was weak and very rapid (180 to 200); the respirations averaged 140 per minute. During the morning brandy was given in doses of ten or twenty drops every half hour and the "heart stimulant" tablets every two hours. As it did not seem justifiable to push these remedies further, and as the infant's strength was already much reduced by the sickness of two weeks, it was thought that the safest aid could be obtained from oxygen. A cylinder was obtained about 5 P.M. and the administration at once begun by holding the mouthpiece pressed to the infant's nostril. At this time the condition was alarming in the extreme, as may be inferred from the fact that the respirations had been 140 all day, and the day before had at one time run up to 160; the pulse was varying between 160 and 180 (a little later it was 200), and the temperature was 103.5° to 104° F. The heart's action was weak, the skin dusky, and the whole condition was so evidently due to lack of proper oxygenation, that it seemed almost self-evident what remedy was needed. The only question was whether the remedy could be satisfactorily applied. But almost as soon as the stream of gas was allowed to enter the nostril the favorable effect was observed. The circulation and general condition improved as markedly as when the gas is given to patients who are able to co-operate in its administration; the duskiness of the skin disappeared, the respirations grew less shallow and slower, and the whole appearance changed for the better.

Throughout the day of the 14th, the oxygen was given every fifteen minutes for five seconds at a time, and during the subsequent night it was inhaled almost continuously; the brandy was given in ten-drop doses every half-hour, and the "heart stimulant" every two hours. Early the next morning the patient turned on the left side for the first time since the involvement of the left lung. The crisis of the disease was apparently reached, as from now on the symptoms gradually ameliorated; the stimulants were diminished by degrees and the food increased. The brandy and oxygen were given in alternate doses every half-hour for a day or two, and not for three days was the oxygen altogether omitted. The patient had a most satisfactory and complete convalescence, and is now a vigorous baby.

THE TYPHOID SPINE.

By JOSEPH N. STUDY, M.D.,
CAMBRIDGE CITY, IND.

There are certain sequelæ of typhoid fever which are known to physicians, but are rarely referred to in standard text-books upon the practice of medicine, and only occasionally spoken of in medical journals.

The title of this subject, so far as I am aware of, was first referred to by Dr. Gibney, of New York, who, at the American Orthopedic Association, in 1889, described a sequela of enteric fever, which he termed the typhoid spine, an inflammation of the periosteum and the fibrous structures by which the spinal column is held together.

The only other reference to such a condition that I know of is in an article published in the *American Journal of the Medical Sciences* for January of the current year, by Dr. William Osler, of Baltimore, who, under the title of "The Neurosis Following Enteric Fever, Known as the Typhoid Spine," reports the histories of four cases, and also three cases of Dr. Gibney. In brief, this condition is spoken of as following enteric fever, and has usually occurred after the patient had so far recovered as to be up and about. It is characterized by pain in the back, which, when any movement is made twisting or flexing the spinal column, is usually of an agonizing nature, often causing the patient to cry aloud. In some of the reported cases fever was observed, while in others it was absent. Usually there was no disturbance of motor or sensory nerves, and further than the

painful back there was no indication of disease in any other part of the body.

I desire to report a condition observed after typhoid fever, which, for want of a better name, I have called the typhoid spine. This case presented some features which are so infrequently seen that to me it was one of more than ordinary interest.

On August 10, 1893, Mr. W——, aged thirty-four, American, occupation undertaker, father of three children, and whose previous health had been excellent, was taken with typhoid fever. October 11th, he was discharged as being convalescent. His sickness was severe, and he had had hemorrhage from the bowels and diarrhœa. His recovery was uneventful until December 13th. At this time he had gained thirty pounds in weight, and had been doing some work, which consisted of a twisting or rotary movement of the spine, occasioned by standing on the rounds of a ladder and using a hand-saw. Following this appeared a painful affection of the back, extending from about the fifth dorsal to the third lumbar vertebra. For over three weeks the pain produced by any flexion or other movement of the spine was intense, and at times caused the man to cry aloud. Almost the entire time was spent in a reclining chair. In attempting to place the patient in bed the pain produced was so great that no persuasion could induce him to make further efforts. It was only because of the loss of sleep and the consequent free use of morphia, that the effort was made at this time.

There was an increase of temperature reaching as high as 103½° F., which continued for ten days, and was followed by rather free perspiration. There was at no time any hyperæsthesia or other indication of either the motor or sensory nerves being affected. No complaint was made of pain in any other portion of the body. At one time a band-like feeling around the waist was complained of for a short time. No tenderness was observed when pressure was made over the seat of pain. Repeated examinations of the various organs of the body and of the urine were made, but were always negative in their results.

After ten weeks the patient has so far recovered as to be out, and says he is almost entirely free from pain.

SOME MINOR POINTS TO BE OBSERVED IN ADMINISTERING CHLOROFORM.

By AARON JEFFERY, M.D.,

RADFORD, VA.

Ever since chloroform and ether have been in general use, the question of which is the safest and best anæsthetic has been debated throughout the country. Recently there appeared in the Medical Record several articles in support of chloroform, among the number an article by Dr. Fisher, of California, headed—"Chloroform in Organic Disease of the Heart." He lays great stress on the slow administration of the drug; and in my opinion that is one of the most, if not *the* most, important point to be observed in its administration.

By observing this rule, the lungs and heart gradually become acclimated, so to speak, and the shock to the nerve-centre is avoided. If a person could be suddenly removed from a low to a very high altitude, I dare say the same thing would happen that often happens during the *quick* administration of chloroform, namely, cessation of the respiration, and as a consequence, engorgement of the heart and death. On the other hand, if the change be gradually made, the person often can stand the change well, and, for the same reasons, the slow administration of chloroform may be tolerated when the quick method would cause death. In the German schools of medicine, I believe they all practise the slow method, and chloroform is the anæsthetic used mostly by them.

There are other minor points that should be observed. The patient's head should be turned so as to allow the tongue to fall to one side. About ten years ago, on one occasion, I came very near losing a patient on account of neglecting to observe this rule. The patient's breathing stopped and the pulse became rapid and weak. I discovered that this alarming condition was caused by the relaxed tongue having fallen to the back of the throat, and thereby shutting off all air from the lungs. The tongue was pulled out by means of a tenaculum, artificial respiration performed, and in a short time the man wa breathing quietly. As a general rule, I think it advisabls to administer an hypodermatic injection of morphine about fifteen minutes before commencing the anæsthetice The nervousness of the patient is thereby lessened, and. the quantity of chloroform necessary to keep the patient anæsthetized is also lessened, to say nothing of the stimulating effect of the morphine on the heart's action.

One should always have at hand an hypodermatic syringe loaded with whiskey or brandy, a phial of aqua ammoniæ, and some nitrite of amyl, to use in case the heart or respiration should fail.

Nothing original is claimed in this article, but I believe if these details are observed strictly, namely, the slow administration of the drug, the previous administration of morphine hypodermatically, the patient's head kept on one side, ammonia, whiskey, and nitrite of amyl at hand, that the deaths from chloroform inhalations will be greatly diminished.

THE EXCESSIVE CONSUMPTION OF TEA AS A CAUSE OF MULTIPLE NEURITIS. REPORT OF CASE.[1]

By WILLIAM PHILIP SPRATLING, M.D.,

NEW YORK.

The etiology of multiple neuritis is quite extensive and varied. In different countries the affection is described under different names. In India, portions of South America, and the East and West Indies, it is known as beriberi. In Japan, where it frequently occurs in epidemics of great severity, it is called kakké.

The causes of multiple neuritis differ in these widely diverse communities. In Japan, the matter of diet has long been held to be an etiological factor of importance. The inhabitants of that country, as we know, subsist almost wholly on a diet of fish and rice, and drink tea to the exclusion of all other beverages. Among sailors on shipboard also, where the disease is frequently found, restricted diet has been regarded as a potent cause.

The causes of the disease, as we find it in this country, are most varied. Among those most usually recognized and active, may be mentioned alcohol, illuminating gas, lead, arsenic, strychnia, and the infectious agents of certain diseases, as typhus, diphtheria, small-pox, malaria, and tuberculosis. Exposure to cold and damp, and overexertion, are likewise causes.

Gowers is of the opinion that "endemic neuritis, as it occurs in Japan, is due to some endemic influence." It is a matter of common knowledge that the Japanese people are the greatest tea-drinking race in the world. It is likewise true that the people of no other country suffer so frequently and so violently from multiple neuritis as the Japanese do. Not only is the disease present with them at all times in an endemic form; but it frequently sweeps over the country in the form of severe epidemics.

Is there any connection between excessive tea drinking and multiple neuritis? I think there is; and for this reason. Tea is a recognized stimulant of the nervous system. Its prolonged and excessive use induces a train of well-marked nervous symptoms, which vary in individuals of unlike susceptibilities. A brief reference to the physiological action of tea, or its alkaloid theine, will show this to be true.

Richardson[2] says, "This alkaloid exercises a special influence on the nervous system, which, when carried to

[1] Read before the Harlem Medical Asssociation, May 2, 1894.
[2] Preventive Medicine, 1884, page 364.

a considerable extent, is temporarily, if not permanently, injured." This author observed the most characteristic effects of tea in "tea tasters," persons who by profession are engaged to determine the qualities of tea by the process of tasting different specimens of strong teas. He found in such persons distaste for food, deficient appetite, nausea, nervous depression with muscular tremors and feebleness, constipation, flatulency, and almost entire inability to sleep.

Wood [1] says: "Chemically, the alkaloid obtained from tea and known as theine is identical with caffeine; indeed," he adds, "most of the caffeine used in commerce, according to Dr. Charles Rice, is obtained from the tea leaf. If, however," he further adds, "the experiments of Dr. Thomas J. Mays are confirmed, theine is not physiologically identical with caffeine." Dr. Mays asserts, as the result of his experiments made on frogs, that theine differs from caffeine as follows: 1. Theine produces spontaneous spasms and convulsions, while caffeine does not. 2. Theine impairs the nasal reflex early in the poisoning process, while caffeine does not, if at all, until the very last stage. Dr. Mays also claims that theine is a powerful local anæsthetic.

Thus we see that all the phenomena observed by Dr. Mays that were induced by theine, including spasms, convulsions, abolition of nasal reflex, and anæsthesia, were purely of nervous origin.

The case I have to report is that of W. S. W——, male, thirty years of age. Usually strong and robust, but suffers at long intervals from very mild attacks of subacute articular rheumatism. Does not use liquor or tobacco in any form. Is extremely susceptible to the influence of alcohol, one-half ounce of any light wine quickly causing flushed face and noticeable exhilaration.

Prior to November, 1892, he had not been a tea-drinker. At that time the habit was formed of taking one-half pint of strong tea at noon, and again about four o'clock in the afternoon. Later the quantity consumed was increased to one and one half pint daily, and the increase became gradual until from two and one half to three pints were taken in twenty-four hours. Six weeks after this indulgence began, a mild tingling sensation appeared in the right hand, extending half-way up the forearm. Small blebs, due to trophic disturbances, appeared on the dorsal surface of the first and second fingers. The skin of the entire hand was slightly hyperæsthetic, and the temperature sense of the member was impaired. At the same time it was noted that the heart's action was feeble and irregular.

An exact diagnosis of the condition at that time was not made. The use of tea was stopped, small doses of digitalis given, the patient directed to take long walks daily, to eat simple, nutritious food, and in six weeks all traces of the trouble had disappeared.

The second attack occurred in January, 1894, fourteen months after the first. For three weeks preceding this attack, strong tea was again used in excessive quantities. The patient was engaged in literary work and took the tea as a stimulating and refreshing drink. The first symptom noted this time was pain in the right wrist, dull, boring, and burning in character. It was ascribed to rheumatism, until pain of the same character was felt in the right shoulder, spreading over the scapula as far as the spine, and running down through the axilla, along the course of the median nerve, as far as the elbow. The brachial plexus was involved, and pressure applied to any part of the axillary space caused intense pain. The chafing of the seam of the undershirt in the armpit caused great discomfort. The median nerve was especially involved. Pressure over it at any point could not be borne. Both of the main nerve-trunks below the elbow suffered. The first disturbance of the temperature sense of the hand was noted when the hand was put in water at a temperature of 50° F. Pain was so great that it had to be withdrawn. The surface of the hand, especially the dorsal portion, became painful to the touch.

[1] Therapeutics, its Principles and Practice, 1892, page 373.

The sensation was described as being similar to that felt when the skin is blistered and again brought into contact with heat. A group of three small trophic blebs appeared over the carpo-metacarpal articulation of the first finger. A similar group, but more numerous, developed just below the styloid process of the ulnar. Between the first and second joints of the phalanges of all the fingers, small, hard, deep-seated nodules appeared. Pressure over these caused intense pain. Picking up or handling hard, firm substances, as a chair or a book, was accomplished with difficulty. There was delayed transmission of pain and temperature sensation. Remak's sign was noticeably present. This was well exemplified by making pressure over the nodules on the fingers above described, or by pinching or pricking any part of the hand, when pain would not be felt for two seconds or more; and when it did appear, grew in intensity, and after reaching its height, would slowly subside.

The motor symptoms were not so marked as the sensory ones, due to the fact that the disease did not progress beyond the inflammatory stage. There was, however, weakness, and quick sense of lack of power when the hand and arm were used. Writing was difficult and could only be done for a limited period of time without rest.

I regret that I was unable to test the electrical reactions of the case. For diagnostic purposes, however, it was not needed.

The treatment consisted of the application of the usual remedies. Good general tonics, and drugs that build up the economy, are frequently indicated. The removal of the cause, whenever found, is, of course, superior to all other forms of treatment combined. In this case, the use of tea was absolutely forbidden; out-of-door exercise in abundance prescribed, the use of light, nutritious food advised, and in six weeks the disease had entirely disappeared.

70 West Eighty-eighth Street, May 1, 1894.

THE TREATMENT OF QUINSY.

By SILAS S. CARTWRIGHT, M.D.,

roxbury, n. y.

Some years since I saw the following prescription in the Medical Record for quinsy:

℞. Norwood's tincture ver. vir..... gtt. xxx.
Morphiæ sulphas..... gr. jss.
Aquæ..... ʒ vj.

M.—Sig. Dose for an adult one drachm, to be repeated according to judgment in one hour, then every two or three hours according to the effect of the morphine.

I have used this prescription several times; in three cases out of four it has aborted the disease; where suppuration has supervened the disease has been more under control. I would give the physician's name and residence but have forgotten it.

The only other treatment has been mild gargles and a cathartic of epsom salts. I have tried other methods of treatment, but this has been the only satisfactory one.

Experiences with New Anæsthetics.—At the meet- of the Académie de Médicine last week, M. Duplay read a report on a case of death by bromide of ethyl in the course of an operation. Hitherto it had been thought that this agent was innocuous, but some recent accidents (two deaths) should render surgeons more circumspect and more prudent in its mode of administration and cause them to take some of the precautions regarded as indispensable when chloroform is the anæsthetic. M. Laborde drew the attention of his colleagues to a new anæsthetic mixture consisting of nine parts of chloroform and one part of ether. It would seem that this combination acts more promptly and with less danger than when either of these agents is employed separately. Further, the active properties of chloroform are attenuated.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, July 28, 1894.

IS THERE A NEED FOR MORE MEDICAL COLLEGES?

IT is so seldom that we have outspoken views in matters pertaining to the general welfare of the profession, in different localities, that it is worth while to make note of them when they are offered, and give them that weight which an honest conviction of the principles upon which they are founded makes manifest. Although such independence of thought is oftentimes associated with unpopularity in affected quarters, it has its wide range of usefulness in the far-reaching indorsement of the majority beyond. It does not matter, for the sake of the principle involved, whether or not a new medical college is to be started in Alabama, or any other State, but the question narrows itself to the necessity of any more medical institutions of the kind anywhere. The discussion on the true point of issue, in the particular case before us, centres upon the possibility of quieting an objector by giving him a place in a faculty.

The failure to do so, however, was emphasized by a circular letter from him, which treats the question in such a general and fair way, that we quote extracts for the benefit of all concerned. The reasons given have an application far outside the limits of the particular State.

Dr. Jerome Cochran, of Montgomery, Ala., is the writer of the letter referred to. He states that the said letter was originally addressed to the *Age-Herald*, but "for reasons satisfactory to all concerned, it was not published in that paper." This will not hinder, however, other than the readers of that journal from a knowledge of his sensible view of the situation.

"It was only yesterday that I saw in the *Age-Herald* of June 10th a list of the professors and lecturers in the proposed new medical college in Birmingham. In the list of lecturers I am surprised to find my own name. What authority you had for publishing me to the world in that capacity I do not know; but it was certainly done without my knowledge and without my consent. Not only so; but it places me in a position of considerable embarrassment; because it must have left the impression in the minds of those who read the statement that I was in favor of the organization of this new medical college. But I am not in favor of it. On the contrary, I regard the establishment of a new medical college in Alabama as in contravention of the best interests of the profession and the people, and if my name has any influence, I should regret very much to have it used for the furtherance of any such enterprise. I do not desire to be misunderstood. I do not object to the establishment of a medical college in Birmingham any more than I would object to the establishment of such an institution in Montgomery, or in Selma. But we have already in this country three times, yes, six times as many medical colleges as we have any need for. In this opinion I am sure that I will be sustained by nine-tenths of the doctors in Alabama—in the South—in the whole of the United States. This being so, the further multiplication of medical colleges is not a consummation devoutly to be wished; and a new medical college in Alabama can by no possibility be of any benefit to anybody except the gentlemen personally connected with it. It does not fill a long-felt want. It does not respond to any demand of public utility or convenience.

"Not only have we more medical colleges than we need, but we also have more doctors than we need. Not one-half of the doctors in Alabama are now able to make decent livings by the practice of medicine. Nevertheless, the exploitation of a medical college is a business in which honorable men may honorably engage. Only let it be well understood that it will not contribute to the welfare of the people or to the aggrandizement of the medical profession."

He further says: "In all this I am not taking any new position. For many years it has been well known in Alabama that I have regarded the medical colleges as in a large measure the natural enemies of our people and of our doctors. In this connection I beg to refer to the two addresses delivered by me before the Medical Association of the State, one in 1870 and the other in 1871, and which were printed in the Transactions for the years mentioned. In one of these I describe the creation of a medical college in these words: 'The process was simple enough. It was only necessary to form a company of seven or eight doctors, build a big brick house, and apply to a complaisant legislature for a charter, and lo! the thing was done. Full-fledged professors grew up in a night like Jonah's gourd; diplomas in high-sounding Latin and on excellent sheepskin could be ordered by the thousand, and the only thing left to do was to get students. But students they must have or perish.'

"We do not have to seek far to discover the cause of antagonism between the medical colleges and the medical profession. It is due to the fact that the great majority of our medical colleges have been built by private enterprise, and have been managed for the private emolument, in money and in reputation, of the men who built them. All this is as in the nature of things we should expect it to be. But let us call things by their right names."

By way of further vindicating his position he very forcibly remarks: "The most interesting chapters in the history of the American medical profession are those that describe the emancipation of the profession from the tyranny of the medical colleges—a struggle that has been going on for the last fifty years, and which is not yet completely won. In Alabama we have for the protection of the people and of the profession against the usurpation of the colleges the medical law of 1877—a sufficient protection as long as it is left us. But if we had had as many medical colleges in Alabama as they have in Tennessee and Georgia, we would have been left, as are the

people of those great States, to the tender mercies of our enemies, the faculties of the medical colleges."

Well and truthfully said, Dr. Cochran; you will evidently have the majority with you, not only in Alabama, but throughout the country.

THE DIGESTION OF MILK.

The importance and value of milk as a diet is acknowledged by all, and needs no exposition here. Milk is not only a very nearly perfect food, but it is diuretic, and its lactic acid has been found to have germicidal properties on the *bacillus communis coli* (Gilbert and Dominici). But despite all that can be said for milk, there are many persons who dislike it, and positively assert that it does not agree with them. The common belief is that it coats the tongue, produces a bad taste in the mouth, and leads to fermentation, constipation, and "biliousness." The physician often has a hard time with these galactophobics. Sometimes he persuades them to try the milk, and the patient is surprised to find that he is not as much disturbed as was expected. But more often the patient returns with the "no better" or "I told you so" expression on his face, and reiterates the tale of his digestive limitations. Then, perhaps, the doctor sets to work to tinker the liquid into more assimilable shape. It is boiled, sterilized, or pasteurized; or it is diluted with water or vichy, or sweetened with malt, or salted a little to taste, or peptonized to non-appetizing bitterness. Matzoon, koumyss, or buttermilk are then perhaps substituted. Not infrequently a moderate degree of success is achieved, but there is always a percentage of failures. We welcome, therefore, any substitute for milk or means of making it more acceptable.

M. Bovet, of Pougues, asserts (*Bullet. Général de la Therapeutique*) that he has succeeded in making milk digestible by adding to it *légumine*. This substance is a vegetable ferment, which, he says, acts upon the casein, turning it into a soluble albuminoid—a sort of lactated peptone. The legumine is also given independently as a food in doses of fifty grammes or more a day. He reports a number of cases in which patients were able to take this combination of milk and legumine when all other foods were rejected.

THE NEMESIS OF "DOC."

A writer in *The National Medical Review* says some words regarding the significance of the title "Doc" which are apt and eloquent, and which, we venture to surmise, come from a heart that has been embittered by some sad personal experiences. "If," says this writer, "it has been your misfortune to be called 'doc,' and if this recognition has become at all general among your friends, you might as well move to some other place. A man may be called a thief, a liar, and a dead-beat, and yet he may prosper and live upon the fat of the land. But once let him be called 'doc,' and his professional success is at an end. We would prefer to spend a night in the station-house, so far as its effects on our professional success is concerned, rather than to have our friends notice our approach by saying, 'There comes doc.' If a man calls you 'doc,' you need never expect a penny from him for any professional services you could render. His answer is sure to be, 'All right, doc, in a few days that will be all right.' 'Doc' means disaster. 'Doc' is the culmination of all calamity. 'Doc' is a catastrophe given at one stroke. 'Doc' is the warning that we have reached the extreme limit of our usefulness. 'Doc' is the hand which points us to the next town. Shun it, my young friend, as you would flee from a Kansas cyclone or a prairie fire. Knock the man down who first dares speak it to you, and call upon the whole medical profession for vindication of your righteous deed."

There are some people, alas, to whom all doctors are just "docs." No amount of dignity in appearance, sobriety in demeanor, superiority in years, wisdom, experience, wealth, position, or morals makes the slightest difference. The doctor is clapped on the shoulder and affably saluted with the damning monosyllable. Hippocrates returned to earth bearing the dignity of supreme genius and wisdom would be simply welcomed back with the same "Here comes doc."

But, after all, "doc" is the Nemesis which pursues the medical profession for clinging to the mediæval practice of affixing always the title "doctor" to the physician's name. Of all men of learning, the doctor alone thrusts his profession into every phase and association of his life. He is always Dr. Brown, M.D. No wonder, therefore, the title has grown so familiar that it signifies little to the educated, and fails to protect against the familiarities of the ill-bred.

MANAGING BOARDS AND TRAVELLING HEALERS.

There is a hospital at Echuca, Victoria, N. S. W. It is very far away, but hospital managers are just the same on both sides of the world. This hospital needed funds, and an entertainment was organized for that purpose. Among the chief attractions was to be "Professor Tarasco, the marvellous travelling healer," who was to cure people for various modest sums, all of which would go to the hospital. The medical board entered a protest against securing the services of such a person for such a purpose; but their protest was almost unanimously unheeded, and the medical board was asked to withdraw its letter. Some of the medical men thereupon resigned.

The affront would certainly justify such action.

The Cutaneous Application of Certain Alkaloids as Regulators of Thermogenesis. — MM. Guinard and Geley have found that of eighteen alkaloids applied in solution or as an ointment to the inside of the thigh of man or of one of the lower animals, four of them, viz., cocaine, solanine, sparteine, and helleborine, have constantly the effect of regulating heat production. This regulating effect is entirely due to the action of the drug on the peripheral nerves, and is entirely independent of absorption through the skin. That this is so is proved by the absence of any such effect by the introduction of the same drug into the system. No trace of the alkaloid was, moreover, discovered in the urine in the above experiments. Again, drugs commonly administered as antipyretics—quinine, antipyrin, phenacetin, sodium salicylate, aconitine, etc.—are ineffectual when rubbed into the skin. The experiments do not show any superiority of the alkaloids over guaiacol.

News of the Week.

The Plague in China. — Surgeon-General Wyman, of the Marine Hospital Service, has received a report regarding the "plague" in China from Dr. Stuart Eldridge, a member of the Imperial Board of Health of Tokio, and Health Officer of the Port of Yokohama. The report is in the nature of a warning. The plague, he says, has been known to be present in the Yun-Nan district of Southern China for at least fifteen years, in form generally sporadic, at times epidemic in malignant form. The disease broke out in February, in Canton, and almost simultaneously was epidemic in Bakhoi, a port at the head of the Gulf of Tonquin not often visited by European trade. The epidemic in Canton steadily increased in March and April, until in the latter month it had assumed gigantic proportions.

The authorities of Hong-Kong, the centre of trade in the far East, half a day's journey from Canton, and in constant communication therewith, utterly ignored the existence of danger until, in the first ten days of May, the plague broke out violently and extensively in Hong-Kong.

Since its appearance in Hong-Kong the epidemic, which is unquestionably a genuine bubonic plague of a most malignant type, has steadily increased until, by the latest reliable advices, the mortality is certainly over one hundred a day; and this despite the fact that at least one hundred thousand Chinese and many Europeans have evacuated the place—the former, in many cases, leaving on feeling the first symptoms of the disease, in the hope of dying in their native villages. At least a dozen Europeans have been attacked, most of them succumbing. Since Dr. Eldridge's report, which was written about a month ago, there has been no marked progress of the plague. If it should reach Japan this country would be in some danger. Still it is a disease that could be easily controlled.

Cabbage and Ice-cream do not go well together in the human subject. This physiological fact was tragically demonstrated by Lena Carey, of Delaware, who on a wager ate a large quantity of cabbage and followed it with four plates of ice-cream. Next day she died.

The Riverside Hospital at Yonkers has received an additional gift of $50,000 from Mr. and Mrs. M. F. Cochran.

Mr. George Meredith, the greatest of England's living novelists, has dedicated his latest work to a physician. In this he follows the example of one of the greatest of England's earlier novelists, Mr. Thackeray.

The State Constitution and the Coroner System.—The obstacle in the way of abolishing the ridiculous and antiquated coroner system of this State by legislation, has thus far been the bare recognition of the office of coroner in the Constitution. "Coroners" are included among the officers who must be chosen by the "electors of their respective counties," and who may be removed by the governor, and they are mentioned a second time among the county officers who were to hold office until the expiration of the terms to which they were elected on the going into effect of the Constitution of 1846. With these exceptions, the office is in no way referred to in the present Constitution, and it is only necessary to expunge the name from two sections referring to county offices to enable the Legislature to reform the whole system of inquiring into the causes of sudden death. There is no doubt that the gentlemen appointed by the Academy of Medicine to co-operate with the Constitutional Convention will see that the proper change is made.

The Columns of *The Lancet* sprout weekly with asparagus items. We had thought that the matter was settled, and that asparagus was to be definitely classed as a diuretic, and to an extent perfumer of the genito-urinary tract. But Dr. Samuel Wilks comes out in an open letter and states that the contrary is true. Asparagus is, he says, in effect anuretic, lessening the urinary flow. When matters of this kind fail to be settled by the languid and ineffectual observations of the Old World, it becomes necessary to call in the aid of the New. Through the columns of the MEDICAL RECORD it was established that the sick do sneeze, and we are sure that our readers can settle with equal positiveness the important question: Is asparagus a diuretic?

The Modern Tendency in Public School management is to abolish devotional exercises, and substitute gymnastics and sanitation. This tendency has reached its extreme in Vienna, where Dr. Kohn has proposed, in order to prevent the propagation of diphtheria among school-children, to have them inhale permanganate of potassium, in the form of a spray, before leaving the classes.

The Cholera prevails extensively on the continent of Europe, cases being reported from Lubeck, Nantes, Berlin, and many places in Russia. In St. Petersburg the epidemic is rapidly spreading, the new cases averaging 200 daily and the deaths 100. There are over 1,000 patients in the hospitals of the city. The disease has also broken out in the military camp at Krasnoe Selo, eighteen miles south of St. Petersburg.

Mr. Gladstone's Eye requires another operation, and he has returned to London to have it performed.

An International Congress for the Protection of Infant Life was held at Bordeaux on July 22, 1895. It consisted of three sections: 1. A physical section, in which all questions relating to societies for protecting infant life, maternal charity *crèches*, children's hospitals, sanatoria, etc., were discussed. 2. A moral section, for the discussion of questions relating to the protection of children abandoned by their natural protectors, apprenticing, orphan homes, and agricultural colonies. 3. An administrative section, in which the Roussel law and all questions relating to the protection of infant life will be studied.

Shorthand in Medicine.—In order to promote the use of shorthand by medical students and practitioners, by enabling them to increase their knowledge at the same time of the art and of their profession, a small sheet of clinical teaching in lithographed phonetic shorthand has been issued by a London firm. The paper, which will be continued if found to fill a need, contains reports of clinical lectures by Dr. Gowers and other prominent London clinicians.

Joseph Hyrtl, the distinguished anatomist, died at Vienna, on July 17th, aged eighty-three. He was Professor of Anatomy in the University of Prague from 1837 to 1845, when he was elected to a similar chair in the

University of Vienna. He was the author of a "Manual of Physiological and Practical Anatomy," and a "Manual of Topographical Anatomy and its Applications."

A Collective Investigation of Quacks has been proposed by Ernest Hart. He asks medical men to send to him the following information: the name and address of the quack, the description of his premises, one of his advertisements, including a copy of each book and pamphlet, and cuttings from the local papers with dates; a memorandum must also be made of the date on which the name, address, and description of the premises is taken down. The member must do this himself, and preserve his original notes. The results of the observations should then be catalogued and arranged by the different branches. It would also be necessary to note the nature and condition of the neighborhood where the quack purports to practise, and his hours of attendance. If this work is carried on all through the United Kingdom, we should then be in a position to call the attention of Parliament to the prevalence of quackery. I admit that the task is a heavy one, but unless some such plan is carried out it will be impossible to expect such drastic reform in the Medical Acts as is desirable in the public interest as well as in the interest of the profession. This class of quacks will scarcely be affected by the hitherto proposed amendments to the Medical Acts.

The American Journal of Insanity.—In a circular dated July 12th, the retiring editor, Dr. G. Alder Blumer announces that the *American Journal of Insanity* has been sold to the American Medico-psychological Association, and will be edited by a committee consisting of Dr. Edward Cowles, of Boston; Dr. Henry M. Hurd, of Baltimore; and Dr. Richard Dewey (in immediate editorial charge), of Chicago; and that until further notice it will be published in Chicago.

The Income Tax and Professional Workers.—It is gratifying to notice that on several occasions during the discussion on the Budget proposals influential speakers have directed attention to the injustice of applying the same rate of taxation to income derived from hard work, and dependent on the life and health of the payer, as is applied to income derived from investments. True, no statesman has yet had the courage or the energy to devise means for remedying this injustice; but it is now so clearly perceived and expressed that its redress cannot be much longer delayed.—*Lancet.*

The Negro as a Hospital Interne.—In the last examinations for position as interne at the Indianapolis City Hospital, a negro was appointed as the best fitted among a considerable number of candidates. The young man is of Massachusetts birth and is twenty one years old. He is a graduate in arts of the State University of Missouri, and received the degree of M.D. from the Medical College of Indiana in this year's class, ranking third in a class of fifty-four, all the others being white. This appointment of a negro, though fairly won, has caused a most bitter outpouring of abuse upon the young man and all concerned in his appointment. His services began in the surgical wards, whereupon the pay patients left and the charity patients made bitter complaint at what they considered an indignity. The general character of the vituperation can be judged by the following extracts from a letter to one of the local medical papers. After bewailing the fact that during this young man's service—which the writer will only speak of as "these circumstances"—no pay patients will enter the hospital, and thereby the city will lose some two to five hundred dollars a month, the letter continues: "The worst feature of this unfortunate situation is that in four months, by rotation, this young man will be placed in charge of the obstetrical department, and white women, whose only crime is poverty, must submit to the unspeakable outrage of bringing innocent children into the world under the touch and manipulation of this son of Ham." He then asks "the Board of Health, who made this appointment, the cringing politicians who prevent the righting of the wrong, and, lastly, all persons who favor this phase of negro equality: How would *you* like to look back to the day of your birth and know that a negro doctor helped to usher *you* into the world?" In conclusion he says: "If the Indianapolis city government does not place this young man where he will only administer to those of his own race, as is fit and proper, they will rob the city treasury, degrade and humiliate many persons, benefit no one, and deserve everlasting contempt from every citizen, both white and black."

The Indian Medical Congress.—The first Congress of Indian medical men will be held in Calcutta, on December 24 to 29, 1894. It is proposed that the work of the Congress should be divided into sections as follows: Medicine and Pathology; Surgery, including Ophthalmology; Obstetrics, and Diseases of Women and Children; Public Health; Medico legal Medicine and Insanity; Pharmacology, specially Indigenous Drugs. Although the Congress is primarily an Indian one, an invitation to assist at its deliberations is extended by the Executive Committee to medical men in this and other countries, some of whom have already accepted. Apart from the medical work of the Congress, which promises to be interesting and instructive, there will be the opportunity of seeing India and visiting its chief cities. The climate during the winter is perfect, the facilities of travel excellent, and two or three months, inclusive of the double voyage, would suffice not only for the work of the Congress but for a visit to most of the chief centres of interest. The journey from London to Calcutta occupies about eighteen days, *via* Brindisi and Bombay, about a week longer *via* Gibraltar and Malta. The P. and O. S. N. Co. have weekly steamers by both routes, the British India Company fortnightly *via* Gibraltar. The Messageries Maritimes run from Marseilles, the Rubattino from Genoa, and the Austrian Lloyds from Trieste. The Calcutta season is at its height during Christmas week, and the committee expect to be able to present a varied programme of entertainments, while a special committee has been formed to attend to the convenience and comfort of visitors. Any desired information may be obtained from the secretaries, Dr. W. J. Simpson and D. M. Moir, 5 and 6 Government Place, Calcutta.

The Medical Golden Rule.—"I feel constrained for once to give you a golden rule. It is never to speak ill of any of your fraternity, whatever you may think. You will do yourself no good, and it will only be thought that you are jealous."—*Dr. Chesterfield's Letters to his Son.*

Congress of American Physicians and Surgeons.

Third Triennial Meeting, held in Washington, D. C., May 29, 30, 31, and June 1, 1894.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Eighth Annual Meeting, held at Washington, D. C., May 29, 30, and 31, and June 1, 1894.

(Continued from Vol. 45, page 762.)

SECOND DAY, WEDNESDAY, MAY 30TH.

Aero-urethroscopy with a New Instrument.—DR. W. K. OTIS, of New York, read a paper giving a history of the subject to the present time and showed his improved instrument. Also cystoscope with eye-piece at a right angle for catheterizing the ureters

DR. BELFIELD showed a tube with catheter curve, with opening at angle and light in tip of tube, for use in deep urethra and neck of bladder, and catheterizing the ureters.

A Needle-holder for the Hagedorn Needle.—DR. BROWN, of New York, presented an instrument of this nature. The very secure grasp of this small pointed holder—equally secure whether a very large or a very small needle be used—is due to the relief from strain which the jaws of the instrument derive from a considerable degree of spring which the handles have just behind the principal hinge. The four separate parts which make up the needle holder are readily detachable. The perineal tube holder serves the purpose of keeping the large rubber tube securely in every position desired, whether this be depth of insertion, or upward, downward, or lateral presentation of the eye of the tube. It facilitates removal for cleansing or making any little adjustment necessary. The patient can himself make any such changes. In case of continuous drainage these apparently minor points are of considerable moment in rendering an uncomfortable condition much more tolerable and manageable. Dr. Brown also showed a modification of the Clover crutch, with cross-bar removed from the field of urethral instruments

Discussion by Drs. Bryson and White.

Stone in the Bladder; Choice of Operation.—DR. WILLIAM H. HINGSTON, of Montreal, Canada, read a paper with this title. In cases where all the cutting operations are equally practical, he prefers the lateral method, and offers the following principles:

1. Lithotresis (and by lithotrity I mean that more perfect method which was foreshadowed by Mercier, in France, and brought to its highest perfection in America). In all cases of adults where the stone is neither too large nor too hard for the lithotrite.

2. Lithotresis, where the urethra is, or can be made, sufficiently capacious for the crushing instrument.

3. Lithotresis in children, however young, where the urethra can permit the passage of a crushing instrument.

4. In very young children the cutting operation is preferable, the precise age at which lithotrity is possible must vary with the calibre of the canal, which in young children greatly varies in its capaciousness and in its capacity; when the urethra in the child is not and cannot be made fit to receive the lithotrite, the cutting operation to be chosen is the lateral method.

5. In cases of stone in the aged, where enlarged prostate not only prevents the stone being seized, but its dimensions being ascertained, we should act as if the calculus were of large size and incapable of reduction, and proceed to operate by the suprapubic method.

DR. CHISMORE, of San Francisco, said the general character of the paper commended itself to good sense. The size and hardness of the stone should not, in his mind, exclude lithotrity. If when the stone is seized and considerable pressure is brought to bear and it does not break, by waiting, the elasticity and spring of the instrument in many cases will work its way through stone. If this fails, should let go and grasp the edge and break off in this way.

DR. POST, of Boston, related a case of stone in the bladder in a child with hip disease, so that he could not be put into the lithotomy position, and the position of legs was such that lithotrity could not be performed. He did a suprapubic operation and found the peritoneum adherent and extending down to the pubes, and was obliged to cut through it.

DR. BANGS, of New York, said that in choosing operation, the removal of the stone is only one thing. There is a disease causing stone, and we are frequently obliged to use a cutting operation for drainage to bladder and pelves of kidneys.

DR. WILLIAM JUDKINS, of Cincinnati, showed a specimen of calculi formed around a stitch left in the bladder after operation by the suprapubic method in a case where it was impossible to get in a crushing instrument.

He thought this case illustrated the stone disease mentioned by Dr. Bangs, and he soon expected to have to do another operation.

DR. WATSON, of Boston, was glad to get the authority of Dr. Hingston in favor of the operation of lithotrity. The array of cases presented by Dr. Chismore the previous day was the most remarkable on record. And he would like to ask Dr. Chismore if he could explain that fact·

DR. CHISMORE, in reply to Dr. Watson, stated that in his cases of seventy-one operations without a death, the good result was due partly to the hardiness of the men and to the fact that the stones were small, and not entirely to the local anæsthetic. He made the operation short, and if necessary completed it at another time.

DR. BRYSON, of St. Louis, said he was in accord with the paper, and the choice of operation depended on the condition of the bladder and urinary organs, and the size and consistency of the stone. When he chose cutting operations, it was because of the condition of the bladder, kidneys, and prostate.

DR. HINGSTON, in closing the discussion, said that he was not wedded to any method. There is no disease of bladder and kidneys where lithotrity is not indicated. The stone causes the condition, and if you remove the cause the condition will improve. His greatest number of cases without death was eighteen.

Urine Leakage and Stricture Formation.—DR. JOHN P. BRYSON, of St. Louis, read a paper of which the following were the conclusions:

1. The close resemblance in the tissue elements, their arrangement, and effect upon the related normal structures, point to an identity of the etiological factor, and give support to the doctrine of urine leakage

2. Observing the prolongation of the urethral epithelium on the fistula wall in an effort to create an adequate artificial channel for urine, and seeing that the epithelium lining the stricture also participates in the battle against urine leakage, we may take fresh hope of radically curing strictures even of the pendulous urethra, by such means as tend to restore or rehabilitate the urethral lining.

3. Merely diverting the stream of urine for a time without such restoration of the lining mucous membrane would fall into the category of palliative treatment, along with urethrotomy and the various methods of dilatation.

DR. TAYLOR, of New York, regretted that he did not bring specimens showing the stricture formation from gonorrhœa to the completion of the process. The pathological appearances do not warrant the theory of urine leakage. There is a tendency always for the stricture to be covered with squamous epithelium, which becomes glazed over and prevents urine leakage. If it was not covered with epithelium it was an ulcer, and the appearance of the cells around an ulcer was not water logged.

DR. BRYSON, in closing, was glad that Dr. Taylor raised the point of urine leakage; all authors referred to strictures as if there were but one form, when there were really two: 1. Inflammatory. 2. Cicatricial stricture

begins with a multiplication of fixed cells. The difference between scar-tissue and stricture-tissue was that scar-tissue is quiescent, while stricture tissue continues to grow.

The Possibility of Overcoming Permanent Stricture of the Deep Urethra without Resort to External Urethrotomy.—Dr. J. Blake White, of New York, detailed the histories of two cases relieved without external urethrotomy, and concluded that, ordinarily, an external urethrotomy might have been thought necessary, and possibly performed; that the spasmodic element, always present to a greater or less degree in deep organic structures, often tends to obscure the judgment of the examining surgeon as to the possibility of overcoming it through less grave procedure than external urethrotomy, and that where a deep organic stricture, not traumatic, is present, thorough and skilful removal of obstructions in the anterior urethra affords the surgeon every opportunity to relieve it by careful dilatation with graduated sounds; since the anatomy of the structure of the deep urethra is such that it yields more readily to dilatation, and absorption is more likely to result in this location from judicious and well directed pressure by the sound. Incision at this point is apt to result in cicatricial formations, which are very apt to necessitate at some future time another operation for the relief of the symptoms which apparently made the first operation a necessity.

Dr. Taylor, of New York, thought the urethral spasm was due to instruments. That if we would use a soft rubber catheter in those cases we would have no trouble, while it resented the approach of the steel instrument.

Dr Martin, of Philadelphia, was glad to hear of the cure of stricture with the sound instead of the knife. He reported a case of stricture of the deep urethra with perineal fistula in a patient who would not consent to operation. He finally got a guide into bladder and dilated up to 10th to 12th French size. The man did not return for six weeks, and the condition was as bad as before. He then dilated up to 26th French, and it had remained at that point.

Dr. Lewis, of St. Louis, referred to a case where he could easily pass a steel sound, but could not pass a soft catheter.

Dr. Bryson, of St. Louis, said that it is hard to separate two processes. When we cut a band of cicatricial tissue we do not destroy the band, but we make dilatation possible.

Dr. Hingston, of Montreal, thought Dr. F. S. Otis's rule of gentle dilatation, with cutting in the old cartilaginous strictures, the best.

Dr. Brown, of New York, said that there are cases in which, after internal urethrotomy, sounds can pass through a previous closed deep urethra. Advises to do internal urethrotomy first and then try sounds.

Dr. Otis said there was no doubt that strictures can be dilated. But in a case like Dr. Martin's he should have done the external urethrotomy. He does not agree with Dr. Bryson, that cutting does not remove the stricture; spasmodic strictures have occurred many times in his practice, and he does not think them due to instruments.

Exfoliation of the Mucous and Submucous Coats of the Bladder, Preceded by Renal and Vesical Calculus.—Dr. Alexander Stein, of New York, referred to the fact that fifty cases have been reported, forty-five in females and five in males. After a careful résumé of the subject, he gave a detailed history of a male case treated by himself, which he summed up as follows:

In summing up this suggestive history, we find that the nephritic colic was invariably referred to the left groin. About six months before he came under observation, he had retention of urine, in consequence of the impaction of a calculus in the urethra. Shortly after this there occurred an intra renal distention from impaction in either pelvis of the kidney, or possibly at the vesical extremity of the ureter. A swelling appeared in the left lumbar region, which was doubtless a hydro- and a pyonephritic tumor. After stagnation of the urine in the pelvis of the kidney, alkaline fermentation was obtained, and a pyelitis was excited which, after the dislodgement of the offending calculus, and the emptying of the pyo nephritic sac per viam naturalem, there was left a favorable nidus for the subsequent formation of crystals of triple phosphates, which, after descending into the bladder, continued their destructive work. The stone was removed by crushing and fragments washed out for a month; there was a relief of symptoms, and then a gradual accession of cystitis, which was followed after a time by the appearance of the exfoliated shreds, which he continued to pass for two weeks, in such quantities as to represent the entire lining of the bladder.

Third Day, Thursday, May 31st.

A Plea for the Excision of the Initial Lesion.—Dr. Edmund E. King, of Toronto, Canada, sent a paper which was read by the Secretary. The following were its conclusions: 1, The early excision of chancres, that is within a few hours after their appearance, will abort the disease; 2, the excision of any unhealed chancre will moderate the subsequent secondary manifestations; 3, that it is the cleanest, least painful, and most scientific method of treating the lesion.

Epithelioma of the Penis.—Dr. Edward Martin, of Philadelphia, detailed a case operated on by himself as a text for his paper, and presented the drawings of a cross section of the growth, showing typical epithelial formation.

Ribbon sections were taken of the whole substance of the penis passing from the centre of the growths backward. The line of demarcation between the healthy and diseased tissue was, as is usual in epithelioma, rather sharply marked. In regard to the etiology of the disease, phimosis is the most common. He quotes various authorities regarding the contagiousness of the disease, and thinks that it is not unreasonable to believe that the contagious nature of a cancer may some day be clearly recognized. He also refers to chancre occurring in the cicatrix of a syphilitic primary lesion, but the scar he thinks simply acted as a focus of lessened resistance.

The prognosis of epithelioma of the penis is now guardedly favorable. Before the epithelioma is fully developed and only folliculitis and a few watery growths present, prompt and efficient intervention will be followed by a radical cure in the majority of cases.

If the disease progresses to the involvement of the inguinal glands, the operations ordinarily resorted to are insufficient and recurrence *in loco* takes place.

As to the operation, this, in the precancerous stage, that is when a case cannot be clearly recognized as cancer, may consist in thorough cauterization, or in excision followed by cauterization. In case the wound does not heal kindly, amputation of the penis should be performed at once. If cross-section shows involvement at point of amputation, extirpation is indicated. In the latter case, when there are any remains of virility, castration is also advisable.

In all cases where the amputation of the penis is required I believe the groin should be opened freely and the entire chain of lymphatic glands should be removed, whether they are enlarged or not. The two points to which the paper was designed to call attention are: 1. That it is not justifiable positively to deny the possibility of contagion in epithelioma of the penis. 2. That where amputation of the penis is required the inguinal glands of both sides should be dissected out, even though they are not appreciably enlarged.

Dr. Taylor, of New York, spoke of the coincidence of cancer in the syphilitic as it appeared after the syphilitic process had ceased. When occurring in a scar, as in this case, it was undoubtedly due to irritation. In reference to contagiousness of cancer, he referred to a case where the man, to do penance for past dissipation, had had frequent intercourse with his wife, who had cancer of the womb, without any injurious result.

Dr. Lewis, of St. Louis, suggested the advisability of castration in these cases, as it diminished blood supply and consequent irritation which would favor recurrence.

Dr. Chismore, of San Francisco, referred to a case which he operated on by excision of the cancerous mass, leaving the inguinal glands. Six weeks later there was no recurrence and inguinal glands smaller.

In concluding the discussion, Dr. Martin, in reply to Dr. Lewis, advised castration when extirpation of the entire penis is performed; when only partially removed there is a certain amount of sexual satisfaction. The question of the contagiousness of epithelioma of the penis is still *sub judice*, and we may have to regard it as a contagious disease. Should advise a partial amputation and then examine the periphery of the stump, and if no cancerous infiltration, there is little danger of recurrence *in loco*. Inguinal glands in all cases should be removed.

Inflammation of the Seminal Vesicles.—Dr. R. W. Taylor, of New York, said that this condition was not recognized until the last few years, and it is mainly through the writings of Mr. Jordan Lloyd that an impetus to its study has been inaugurated. The affection is almost always secondary to gonorrhœa, occurring in the third or fourth week, or to hyperæmia of the posterior urethra due to masturbation and venereal excesses, or to inflammation of this region due to traumatism, catheterization, endoscopy, and strong injections.

Symptoms are similar to those of posterior urethritis, and those given as diagnostic of the several forms of prostatitis.

Course is similar to epididymitis, and at the end of a week or ten days the symptoms become ameliorated and resolution sets in.

Chronic Seminal Vesiculitis.—This form occurs when resolution fails in the acute form. The symptoms are usually obscure and vague. These disturbances are mainly of two forms: First, those of lowered power; and second, those of erythism of the sexual organs.

Diagnosis can only be made by rectal examination. The patient should bend body forward, standing with feet about a foot apart. The examiner can place foot on chair. Elbow on knee to get pressure and overcome the perineal muscles. The bladder should be full.

Frequently the amputated vas deferens is mistaken for the seminal vesicles.

Treatment.—Leeches to the perineum, injection of cold water in the rectum, and packing rectum with ice if the procedure is pleasant to the patient; opium in suppositories, diluents and saline cathartics may be administered if required. Should an abscess form, it may be reached by means of a long incision just anterior to the anus, care being taken not to cut urethra, prostate, or rectum.

Treatment of the Chronic Forms.—By good hygiene, tonics, and the treatment of posterior urethritis, if it exists. He does not agree with a recent paper of Dr. Fuller's, of New York, and shows two anatomical specimens to prove that the seminal vesicles are so placed that it is impossible to reach by the finger sufficiently to milk or strip successfully.

Dr. Allen, of Boston, said that diagnosis could only be made by rectal examination, as the urinary symptoms were not characteristic. In the treatment of terminal vesiculitis, he had been discouraged by Dr. Taylor's anatomical demonstration of the normal position of the seminal vesicles and the inability to milk them. He had witnessed in some cases that after squeezing there had been diminution in size.

Dr. Martin, of Philadelphia, said he had been trying for some time to examine the seminal vesicles in all cases of epididymitis, and in a few cases only had he been enabled to make out the seminal vesicles. And in these cases there was the presence of disease or chronic enlargement, and that it had been impossible for him to make out by rectal examination a normal seminal vesicle. He showed several drawings representing what he had felt in certain cases. In most cases the symptoms were those of posterior urethritis, but in three cases pain was referred to the hip of corresponding side and radiated down only to surface of thigh. He had found that rectal injections gave the greatest relief, and for examination the partial bending of the body was the best. In some cases the lithotomy position was good.

Dr. Brewer, of New York, spoke of pressure in chronic cases being followed by the ejaculation of a clear fluid which rapidly coagulated. The specimen shown by Dr. Taylor proves that we cannot strip the seminal vesicle completely, but by pressure had diminished the size and found discharge containing spermatozoa from the urethra, and in these cases had obtained an improvement.

Dr. Allen, of Boston, would like to put himself on record as agreeing with Dr. Martin in the difficulty of feeling the normal seminal vesicles, but regarding the treatment he agrees with Dr. Brewer.

Dr. Hayden, of New York, had for some time been examining cases at the Vanderbilt Clinic, and added his testimony to the difficulty of feeling the normal seminal vesicle. He was able to feel them only when there was a prostatitis or epididymitis.

Dr. Bangs, of New York, was glad to hear that others had had difficulty in feeling the seminal vesicles, as he could only feel them when enlarged. Yet we can express a fluid, but he was not willing to admit benefit from stripping.

Dr. Weir, of New York, said that within the urethera, the last year, his attention had been called to perineal abscesses from diseased seminal vesicles. They can be reached and removed, if necessary, by a transverse incision in front of anus until we reach cellular space, and through this reach the vesicles, and he had removed those that were tubercular.

Dr. Belfield, of Chicago, called attention to the importance of the sinus pocularis, which varies much in size, and when swollen would produce swelling where we would expect to feel the beginning of the seminal vesicles.

Dr. Bryson, of St. Louis, said the anatomical demonstration called to mind conditions seen several times. He was astonished to find that the vas deferens was so large, and was probably frequently mistaken for chronic enlargement, or for tuberculosis. There was a condition caused by seminal engorgement, and the symptoms were relieved by emptying a portion of the seminal apparatus. This occurred in free livers who over-indulged in sexual intercourse. They would complain of pain in rectum, which was almost constant, not due to local causes. But by introduction of the finger into the rectum and emptying the distended pouch there would be complete relief from the pain.

Dr. Chismore reported a case where he could milk, from a sac occurring on either side, ʒ j. of fluid containing an abundance of spermatozoa.

Dr. Taylor, in concluding the discussion, stated that we should be careful in making pressure on distended sacs felt per rectum. The amputation of the vas deferens was sometimes so marked that it could easily be mistaken for the seminal vesicles.

Surgical Interference in Tubercular Kidney.—Dr. John P. Bryson, of St. Louis, read this paper. In 174 cases of tuberculosis of the genito-urinary tract observed by the author, only 18 gave unmistakable evidence of involvement of the kidney. He gave in detail the histories of several cases treated by surgical methods, and gave the rules usually followed, given as a guide for surgical interference. The conclusion he had arrived at was, to operate only in cases of emergency. The probability of trouble in the other kidney, its absence or the presence of chronic nephritis, made the operation a very serious one. Also the fact that there was probably tuberculosis of other parts of the genito-urinary tract, or even of the lungs, even to drain a tubercular cavity in any part of the body was of doubtful efficacy. To remove a stone or to open an abscess which is not sufficiently drained by ureter, or to remove a suppurating kidney which is affecting the whole system, when we can assure ourselves of

the soundness of the opposite organ, are the only surgical interferences he considered justifiable.

Dr. Bangs said that in closer study of genito-urinary tuberculosis for the past two years he had become more conservative. Good hygiene was the only cure for tuberculosis, and that combination of gases known as "fresh air." Vesical tuberculosis is made worse by instrumentation. He had performed all kinds of operations, but the result was not good. He sends those cases away, Southern California is a favorite place, the warm climate is less stimulating to kidneys, and is therefore preferable to cold. The effect of operation or other traumatism is to make the condition more acute. He applied same rules to tubercular testicles. In the cystoscopic examination of the bladder he frequently found a pulpy condition, rarely only can he find ulcers. He had begun to look upon that condition as tubercular.

Dr. Keyes, of New York, had not made a special study of genito urinary tuberculosis, but thought the surgeon should stand aside and operate only in emergency; there was too much surgeon and not enough medicine in these cases. He has tried surgery, and it failed to help him. Transplantation of the patient was the last means of cure. He did not consider the pulpy condition spoken of by Dr. Bangs always due to tuberculosis. He had never seen it above, always at the base of bladder; bleeds on contact with instrument. He had seen it in strictures and pyelitis where the base of the bladder is bathed in pus, also in tuberculosis.

Dr. Belfield, of Chicago, added his testimony to non-interference in tuberculosis of genito-urinary tract. He had operated eight times, and there was only one case that gave him any satisfaction. That was one in which the drainage was kept up eighteen months. Later died of general tuberculosis. Reported a case of peri nephritic abscess which was aspirated, and sent to a suitable climate with improvement.

Dr. Bryson, in concluding the discussion, said he did not think there was characteristic appearance of the base of the bladder in tuberculosis. The question of involvement of the other kidney is very important. He hoped that the new instrument shown yesterday by Dr. Belfield might help us; also the presence of albumin and casts were important in making a correct diagnosis.

Cystitis and Pyelonephritis, Due to the Colon Bacillus, Requiring Nephrectomy.—Dr. F. Tilden Brown, of New York City, related a case which presented in the surgical service of Dr. McCosh at the Presbyterian Hospital, and reported by Dr. Brown to bring out an expression of opinion regarding the importance or non-importance of the colon bacillus as a pathological agent. An interesting feature of the operation was rupture of the renal artery, attended with very serious hemorrhage, which was successfully controlled by long clamps left in place for fifty-eight hours.

S. W. D——, male, aged forty; widower; United States; masseur. No rheumatism, tuberculosis, gonorrhœa, or syphilis. History; In 1886 sustained an injury to the left side by a fall, which probably injured somewhat the left kidney, as slight functional impairment of urination and sexual powers followed. He then began treatment by the passage of sounds. At the end of the fourth month of this treatment he was conscious of being hurt by a larger sound than had been passed before. Ten minutes later he noticed hæmaturia. Cystitis promptly supervened, and he entered a hospital where, at the end of ten days, he was cured. Returning to his former doctor he submitted to the introduction of a sound, and the next day returned to the hospital with a relapsing cystitis, which soon extended to a left-side pyelitis. He was confined to bed for three weeks. He had a great deal of pain and occasional hæmaturia. After a while he noticed that the urine would at times be rather scanty and comparatively clear. Again the urine would suddenly increase in quantity and contain a good deal of pus.

This state continued for two years, when in 1890 he first noticed an enlargement in the region of the left kidney. This abdominal tumor was not permanent, but regularly subsided after a brief period of polyuria attended with pyuria. In September, 1893, the patient substituted for boric acid solution, as a vesical lavage, peroxide of hydrogen, twenty per cent. solution. Immediately after its first employment he was seized with a chill; high fever and sweating ensued. At irregular intervals every few days he now had a repetition of these chills. He noted extreme distention of the abdominal tumor, followed by its disappearance, and increased quantity of urine. Four such attacks were noted between September, 1893, and January 23, 1894, when he entered the Presbyterian Hospital. At this time his temperature was 98° F.; pulse, 84; respiration, 20.

Physical examination was negative, except that on the left side and well upward border of the ribs, on deep palpation, some pain and resistance could be detected. As the tumefaction he had himself been able to notice did not now exist, he was kept under observation until February 20th. During this time his urine, drawn by sterilized catheter, gave a pure culture of colon bacilli grown on agar, and tested by reaction on milk. The specific gravity of urine was 1.020, acid, albuminous; contained pus, and occasionally blood.

During the week previous to February 20th, pain in left side has been quite constant. Abdominal distention has increased, and a tumefaction in the left kidney region has been quite marked.

Nephrectomy by Dr. McCosh: Ether. During the operation many firm adhesions are met with after the ureter has been ligated and divided, and while detaching the upper segment of the large pyonephritic mass the renal artery is ruptured. During a critical hemorrhage the vessels are caught in long clamps, which are left in place forty-eight hours. A slow but uneventful convalescence ensued. The colon bacillus is again cultivated from the removed kidney, and again from the urine on April 2d, and again on May 23d. The patient has gained twenty pounds. The urine is free from albumin.

Point for consideration: Was the left kidney damaged by a previous traumatism, and thus rendered susceptible to ascending infection at the time of acquiring cystitis? And was the cystitis due to a trauma inflicted upon the posterior urether by a sound, and to a simultaneous implantation of septic matter in the form of the bacillus colli communis?

Is the continued presence of the colon bacillus in the urine, despite bladder irrigation with antiseptics, to be ascribed to the blind canal made of the ligated ureter? Is entire removal of the ureter to be advocated in nephrectomy for septic matter? Does the presence of the colon bacillus at present render the patient more liable to a pyonephrosis of the remaining kidney in case it becomes impaired by traumatism or disease?

Fourth Day, Friday, June 1st.

Tumor of the Testicle.—Dr. R. W. Taylor, of New York, showed drawings of tumor of testicle removed by him. The history was as follows: N. D——, aged twenty-seven; United States; brakeman. Had had gonorrhœa twice. A year ago patient said he had a chancre, and about the same time he noticed a small hard lump at upper part of right testicle, increasing steadily in size. About six months ago he was struck in the testicle by a peach, since which time he thinks the tumor has grown more rapidly.

On admission to hospital the testicle was enlarged to about the size of two fists. It was hard and painless, the inguinal glands very large and hard. The testicle was removed by Dr. Taylor, and was adherent to the scrotum, the inguinal gland was not removed, as the patient objected. He was discharged cured in a month. The tumor was examined by Dr. Van Giesen, of the College of Physicians and Surgeons. Section showed: 1. portions of the tumor a perfect type of adenoma; 2, a less

perfect form of adenoma on the border line of carcinoma; 3, sarcomatous tissue; 4, hyaline cartilage.

This disease begins slowly and insidiously, forms a large, indolent, smooth, oval, dense, and sometimes elastic, not painful or tender, surface, usually smooth, and even later may become bassy and fungating; sometimes there is hydrocele, rapidity of growth; when large produces a dull, dragging sensation; usually begins in early life. Conche, in a study of thirty cases, in twenty-four of which the observer notes the affection developed between the ages of twenty and forty. Uttial Johnson described a case in a child, two years and nine months of age, in which the trouble began at the third month of life.

Dr. Bangs asked if Dr. Taylor made the diagnosis at first. Dr. Taylor replied that he gave internal remedies for syphilis, but the tumor got worse and produced a fungating mass.

Dr. Bangs then detailed a case in which there was no venereal history, the patient was in general good health. There was an ulcer on anterior surface of scrotum appearing like a malignant growth, had an indurated base and bled easily; necrosis of the central portion took place, a portion was removed, and the pathologist sent report of epithelioma. The man refused operation, but the case healed up entirely.

Dr. Bryson, of St. Louis, said that in malignant and tubercular growths the exhibition of potassium iodide made tendency to bleed greater. He had never seen a case of simple growth—always more than one element. The surgeon had this before him. Make diagnosis between syphilis and these growths by antiseptic treatment; if not syphilitic or tubercular should be removed. Commends non-removal of inguinal glands, although it does not agree with modern surgical principles. He would like to ask Dr. Bangs his rules.

Dr. Bangs replied that he removed all enlarged neighboring glands in all cases.

Dr. Keyes, of New York, wanted to ask if in the case reported there was involvement of the scrotum. For if the tumor is confined to testicle and cord, it returns in peritoneal glands. But if the scrotum and surrounding tissue are involved, inguinal glands should be removed.

Dr. Bell, of Montreal, detailed a case of multiple tumors of the brain, and the question of syphilis was considered. Later there developed fibrous growths of the epididymitis, the right side grew slowly and became as large as the tumor described by Dr. Taylor, and showed multiple growths. Growth on the other side did not increase, but later in cord began a large enchondroma which has now begun to fungate.

Dr. Taylor, in concluding, said that he had given the patient antiseptic remedies for a while. His duties as a brakeman caused frequent contusion and irritation of the testicle. The tumor was fungatory and the inguinal glands were enlarged. They had grown smaller since removal, as they frequently do in epithelioma of the penis. Perhaps the enlargement is purely inflammatory. He believes in thorough removal of inguinal glands in such cases.

During How Long a Period is Syphilis Communicable?—Dr. James Bell, of Montreal, reported a case which was thoroughly treated, and married two years and eight months after development of secondary symptoms. During this time he took treatment regularly and showed no evidence of the disease. His wife contracted genital chancre, and developed constitutional syphilis. The author gave history in order to show: 1, That the husband was properly treated, and was, as far as could be seen, free from the disease when he married; and 2, that there can be no doubt as to the diagnosis in the case of the wife. For the rest I believe the husband to have been perfectly honest in the matter, and the wife to have been in every respect above suspicion. In my opinion this must have been a case of blood inoculation.

The second case, in which a man contracted syphilis a few years before he was married, and before the sore appeared the wife became pregnant. She never showed any symptoms of the disease, although she was given protoiodide of mercury pills up to time of delivery. She remained in good health and was delivered in full term of a fine healthy child, which she nursed for six months, when her milk failed and she was obliged to wean it. The child (now nine months old) has never shown a sign of syphilis, and is a typically healthy, well-nourished baby.

Dr. Taylor was very much interested in the two cases, especially the first. In these cases we must eliminate extra-genital infection. It was either a case of great pertinacity of the length of the infecting period, or there was a lover somewhere, and he was inclined to the latter view.

Dr. Bangs thought that as the time was only two years and eight months, it was not unusual for infection to occur.

Dr. Keyes wished to put himself on record as thinking that infection, at least up to the end of the third year, was quite possible.

Dr. Judkins, of Cincinnati, related a case where a man had chancre and wife aborted, although impregnated before the development of the primary sore.

Dr. Bell, in concluding, stated that he was as sceptical as Dr. Taylor, but if there was ever a case where you could trust your evidence, this was surely one.

Dr. Chismore made a few remarks, resigning the chair to Dr. Bangs, the newly elected President. The Association then adjourned until the following year.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Eleventh Annual Meeting, held in Washington, D.C., May 29, 30, 31, and June 1, 1894.

(Continued from Vol. 45, page 763.)

Second Day, Wednesday, May 30th.

Climatic Treatment of Phthisis.—Dr. H. B. Moore, of Colorado Springs, had sent a paper entitled "A Plea for the Earlier Recognition of Pulmonary Tuberculosis, and the Adoption of Proper Climatic Treatment." Owing to the absence of Dr. Moore his paper was read by title.

Three Years' Experience in the Sanitarium Treatment of Pulmonary Disease near Boston.—The second paper was read by Dr. Vincent V. Bowditch, of Boston, with the above title. He presented the results of the treatment of pulmonary disease for three years at the Sharon Sanitarium, near Boston. He referred to the well-known Frankenstein Sanitarium, near Frankfort-on-Main, Germany. It is built on an elevation of fifteen hundred feet above sea-level. It was a famous resort for the wealthy classes. The Sharon Sanitarium was on a hill four hundred feet above sea-level. It was for the working classes, largely shop-girls. He referred to the City Sanitarium established in New York by Dr. A. L. Loomis, and Dr. Charles Quimby, of that city.

It goes almost without saying that the climate of New England is deemed unfavorable for consumptives What can we do for the poorer classes? It has been cod liver oil, cough sirup, and advice about air and food. Left to old-time methods they slowly fail. The ordinary American country boarding-house is not suited to such cases, they are badly ventilated and the food is badly cooked.

The building at Sharon is a beginning, it can accommodate nine patients, all females. It was purposely constructed for an abundance of sunlight and pure air. Every room is freely ventilated. One patient in a room. Building has broad piazzas, where patients are kept out in the pure air. No carpets or mats within to hold dust. No sweeping allowed. Damp cloths are used. Sputa are destroyed. Cups used for that purpose are burned.

The Sharon Sanitarium opened February 9, 1891. Of 48 patients 8 were bronchitics, the remaining 40 had various forms of phthisis—10 had been discharged with the disease arrested. In no case did he use the term cure. The majority had been away from eighteen to twenty-four months. All reports from them were favorable. In

several cases both lungs were involved. Some of these left improved. In the 8 arrested cases bacilli were present in but 3. He often found that the bacilli were not present in cases presenting all the evidences of phthisis, *i.e.*, cough, hemorrhage, sputa, malaise, and night-sweats —in fact, all of the usual symptoms, but in certain cases no bacilli. One case had been in two years, and had gained twenty-eight pounds; another got fat and well; another had had cough and hemorrhage, had gained fourteen pounds and a half in four months. Now she is in California, with an excellent prospect for recovery. In some twenty-five per cent. the disease seemed to be arrested, and there was general improvement in thirty-three per cent.

Bacilli had been found in cases classed as improved. In six cases of this nature the results had been very satisfactory.

He advocated the sanitarium form of treatment. Previous to opening the Sharon, he feared that having such patients in a community would be unfavorable to them. Experience had shown his error. What was the effect of the proximity of patients one to another? At first, it caused depression, but it soon wore off. They are kept under control, hence the direct benefits of such a system as the sanitarium treatment, under skilled management. All can be carefully watched. It was his rule to receive cases where the early symptoms were present. If they failed to improve in a few weeks, he advised them to return to their homes.

Referring to methods of treatment, daily visits of the physician—a sanitarium should have a resident physician. Their chief aims were fresh air and good food. He deems them absolutely necessary for recovery. Exercise within fatigue, rest in the open air, even in the coldest days in winter, patients being carefully wrapped.

As a rule he avoided drugs. Cabinet treatment and pulmonary gymnastics were most valuable. He had no faith in the germicidal action of drugs or vapors. He was not wholly convinced of the value of tuberculin.

In making a brief report on three years' work, he endeavored to leave out the personal equation. Our sole aim should be to do our best for our patients, and in reports to deal with the truth and nothing but the truth.

Dr. Von Ruck, of Asheville, S. C., deemed Dr. Bowditch's experience and observations valuable. Climate is not so important; it is not so much where it is done, as how it is done. While practising in Ohio, he had had about the same results as those given by Dr. Bowditch in fifty-eight observed cases. In twenty-five per cent. there was arrest, and improvement in a third of all under observation. Benefit may be had at home if patients will do as they are instructed.

He did not concur in Dr. Bowditch's views regarding the value of tuberculin. He uses it still, and to day has greater faith in it than ever. Early cases of phthisis want to wait. They invariably think others worse than themselves. Tuberculin applied in the earlier cases, as recommended by Dr. Koch, in his hands gave excellent results. It has a stimulating effect on the tissues. It can be pushed to produce congestion, some using as much as 100,000 milligr. in a month. Such treatment simply does harm, and was not indicated by Dr. Koch. It was overdone. Using tuberculin in the smallest doses gives an effect in from five to ten hours. Where fever is produced the limit of the dose has been used. He firmly believed that the results will be as good as Dr. Koch led us to hope for, and which the speaker firmly believed we would attain.

Dr. J. H. Musser, of Denver, Col., said that we had reached a time when, if tuberculosis is properly managed within certain limitations, it might be deemed a self-limited disease, and the tendency is to cure.

Plans and sanitaria such as those advocated by Dr. Bowditch, deserved the warmest encouragement. Sanitaria within the limits of cities for the poorer classes. If a sanitarium is not properly conducted it will fail. Careless methods will kill it. Reference was made to the infectiousness of the disease.

Dr. Quimby, of New York City, gave an account of the founding of the New York Sanitarium, and what they hoped to accomplish. A lady well known in New York, noted for her charities, had enabled them to give the scheme form and substance. He was of opinion that hitherto too much had been said relative to phthisis, and too little as to the treatment of phthisics. The object of the New York Sanitarium was to relieve the working classes, and aid and advise those having a fortnight's holiday in the year. The consulting staff of the sanitarium would be requested to see all cases on entrance and make a forecast as to their probable expectation of life. This he wanted for the purpose of comparison. He outlined what they hoped to accomplish.

Dr. Curtain, of Philadelphia, spoke of some results at the Philadelphia Hospital, in the phthisis ward. During 1888 and 1889, the patients therein had tubercular sputum. In 1890 influenza appeared, when half of the old cases died. In 1891, or after the influenza epidemic, out of 28 cases 15 had no tubercle bacilli. He conducted a number of post-mortems. Ulceration of the lungs was found, but the closest examination of the tissues failed to detect bacilli Recently a German bacteriologist had found a new bacillus, different from the tubercle bacillus; this, he thought, might explain these cases.

Creosote, Guaiacol, and Benzoyl of Guaiacol in Phthisis.—Dr. Roland G. Curtain, of Philadelphia, read the paper. He gave a *résumé* of his hospital experience at the Philadelphia Hospital, stating that one object was to elicit a discussion on the treatment of tuberculosis by creosote and guaiacol. Dr. Glasgow, in 1891, read a paper on the action of guaiacol. In 1892 Dr. Jacobi, of New York City, dealt with the treatment. Twelve years ago he, the reader, had used Declats's syrup of phenic acid. Guaiacol and phenic acid gave much the same results. Subcutaneous injections of phenic acid were very painful. One patient frankly said that he preferred death. In his experience, as the result of the use of phenic acid, there was an improvement in the appetite and an increase in flesh, less dyspnœa. Speaking of beechwood creosote, he said that it and guaiacol chemically have much in common. Dr. J. J. Whittaker had published results in 1893. When creosote is pure it is harmless and easily borne by the stomach. It has no effect on the bacilli. Some patients take small and others large doses. Creosote may produce hæmaturia. In those who bear it best as far as the stomach is concerned, increase in weight follows. In acute phthisis with high temperature, no benefit results from guaiacol. The class most benefited is that where there is slight fever and poor digestion. Dyspepsia is cured by phenic acid; also greatly benefited by guaiacol. He uses the latter in the form of pil's. It acts well in chronic ulceration of the lungs. He does not believe that it has any specific effect on the lungs.

Benzoyl of guaiacol was introduced by a German physician. He has not found it any better than guaiacol, and it is expensive. He does not deem it as reliable as guaiacol. Guaiacol is not so liable to produce irritation of the kidneys; when pure you know what you are administering.

Dr. A. L. Loomis, of New York City, did not believe that any of the agents named exert any special action or effect in the disease. In many cases the patients seemed to do just as well without such remedies. When introduced into the stomach there is no evidence that they have any other effect than to improve the digestive powers in a certain class of patients. Some patients were saturated with creosote.

Dr. Robert H. Babcock, of Chicago, had used both creosote and guaiacol. Some patients stood them well, others did not. He recalled a case where one hundred and fifty drops had been given in twenty-four hours, with benefit. Previously there had been hemorrhage. She was a young woman. There was a cessation of the

symptoms, and the physical signs all improved. Many patients cannot tolerate it. It allays fermentative processes in the digestive tract. Guaiacol is used after meals. He kept it up until the urine became of a dark-green color, then reduced the dose to one-half, then gradually began decreasing it. Some patients cannot take either.

Dr. Von Ruck, of Asheville, S. C., used creosote four years ago, hypodermically. In four cases, who persisted in spite of suffering, he continued the remedy for two months, they received four grammes a day. He watched the urine, tubercle bacilli were present in all the cases. It had no effect on the bacilli. He was satisfied that they got good results from creosote. It was particularly beneficial in bronchial cases, also of marked benefit in gastro intestinal cases.

Dr. W. M. Gibson, of Utica, N. Y., found that creosote had a direct effect on the blood. Following a moderate dose of creosote after a meal, there is an increase in the leucocytes, producing, he said, better phygacytosis; a count of the corpuscles would prove it.

Dr. Elksner, said that in hospital and private practice he had got very good results with creosote. He said that it was most difficult to make an early diagnosis. In many cases no bacilli were present, unless there had been infiltration in the lungs; there must be breaking down to get the bacilli.

Dr. J. B. Walker, of Philadelphia, deemed the odor of creosote in the breath of such patients very objectionable; said that whether the skin will take it in or not, the skin will give it out; that such people in street cars and elsewhere were unpleasant. If not anti-bacillary, why give such large doses? He believed it to be anti-catarrhal, and that it has a modifying effect on the tissues. It does not kill the tubercle bacillus.

Dr. A. L. Loomis had found tubercle bacilli without destruction of tissue. They may be present in a patient without any destructive changes in the lungs, or air-passages. He had got bacilli in a case where the lungs were unaffected; he mentioned the case while examining the chest of a young man; he had quite a profuse hemorrhage, some blood was secured, it contained a little mucus. In it were found a large number of bacilli; again he examined the chest carefully and got no evidence of pulmonary disease. The patient had hemorrhages for three or four days, the blood gave bacilli; there was no expectoration, yet bacilli were found; that was two and a half years ago. Man now seems well. Bacilli may lodge in the bronchi. This may occur without their entering the lung tissue. Tubercle bacilli may get into the lungs through the lymphatics and the blood-vessels. In the bronchi they cause local inflammation. It may be a long time in any case before there are real destructive changes, and when such do occur we get the ordinary symptoms.

Dr. Elksner respectfully begged to differ with Dr. Loomis, he thought that previous tubercular infiltration was possible, and then necrosis of the vessel. The majority of cases do not give us the presence of tubercle bacilli. Even in miliary cases you have great difficulty in making a diagnosis between phthisis and typhoid fever.

Dr. Loomis, in reply, said that if a patient has symptoms of bronchitis, no bacilli will be got. He would hesitate to pronounce a case one of tuberculosis unless the sputum gave bacilli. He was not criticising the views of others; merely relating an experience in his practice.

Dr. Glasgow deemed creosote very valuable. He had not noticed any kidney effect. He gave from two to seventy minims a day, depending on the patient; one minim seemed to poison some. The creosote he placed in a little whiskey, and that was mixed with milk and cream. He got striking results in cases of bronchial phthisis and in alveolar phthisis. Creosote does not have any effect on the bacilli, but he thought that it has an effect on the poisons they generate. He also believed in the good result of inhaling the vapor of creosote at night.

Dr. Curtain closed the discussion, and expressed his satisfaction with the many views elicited.

State Prevention of Phthisis.—Dr. Frederick I. Knight, of Boston, read a paper entitled "Shall Anything be Done by Legal Authority to Prevent the Spread of Tuberculosis?" Twelve years since the real nature of tuberculosis was made public, but little seems to have been done to cope with the disease to prevent its spread. He reviewed the methods recommended by various boards of health, referring to the action of the Pan-American Medical Congress of 1893, the American Public Health Association of 1893, and their action. The method adopted by the New York Board of Health of February, 1894, was deemed an advance. Its manifesto he read *in extenso*. In his State, Massachusetts, he deemed the time right for its practice. The Board of Health in Massachusetts had issued a bulletin and a leaflet covering the ground. The dangers now so well known he reviewed. Danger of sputa-infected cattle and milk.

Dr. Bowditch, of Boston, fully concurred in the views held by Dr. Knight. He said that we want boards of health to take the happy medium between two extremes. The poorer classes should be under the observation of such boards, the better classes have their physicians.

Dr. Von Ruck referred to the results at the Loomis Laboratory, New York City. Also to Tissini's work. Out of fifty six autopsies made by him in ten or twelve death was due to accident. In them tubercle bacilli were found in the bronchi. He referred to the disease-resisting power of men who ward off phthisis and other diseases when well—as in the cases mentioned, had warded off phthisis; but where the *vis medicatrix naturæ* is lowered by typhoid fever or influenza, in such phthisis finds a foothold. He fully concurred in the views expressed by Dr. Loomis as to bacilli being present where there were no evidences of pulmonary disease.

Dr. John Winters Brannan, of New York, referred to several years' work in New York City on this theme. The timely action of the State Board of Health of Michigan pleased him. Its literature used the proper terms. He said that tuberculosis was not contagious in the old sense of the word. The Michigan Board of Health had been very happy and wise in stating that it was "a communicable disease." The New York Board was prepared to use the word "contagious disease," but, adopting the wise course of Michigan, used the word "communicable," instead. Tuberculosis is a communicable disease.

He referred to the excellent work done by the Board of Health of New York in dealing with diphtheria. The Board assisted New York physicians, and by its judicious action had the warm sympathy and countenance of New York practitioners.

Dr. Wolcott, of Boston, endorsed Dr. Knight's views, and deemed the New York method good, an advance in the right direction.

Dr. Andrew H. Smith fully endorsed Dr. Knight's statements and views. He was in favor of securing the end sought—protection—with as little friction as possible.

Dr. Knight closed the discussion. He was very much pleased that so large and influential a meeting endorsed his views. He offered the following resolution, to be submitted to the Congress the following day:

"*Whereas*, The American Climatological Association was founded, among other objects, to promote the study of the nature and treatment of diseases of the respiratory organs; and

"*Whereas*, Tuberculosis is the most fatal cause of such diseases; and

"*Whereas*, Modern research has placed this disease among the infectious, and hence, to some extent at least, among the preventable diseases;

"*Resolved*, That this Association do strongly recommend all boards of health of this country to adopt means tending to the restriction of the disease."

THIRD DAY, THURSDAY, MAY 31ST.

DR. ISAAC HALL PLATT, PRESIDENT, IN THE CHAIR.

The Condition of the Heart in Diabetes, and its Relation to Diabetic Coma.—DR. LEONARD WEBER, of New York, read a paper with this title, which was based upon a study of sixty cases in his practice. The majority of the patients were over forty five, and most of them were women. He reported two cases in children—one case in a child aged twelve, due to scarlatina, death occurred three months later. Another case in a child following a large use of potassium bromide. In cases after middle life there were no recoveries. The duration of the disease was from three to twenty years

A complication of renal disease renders the cases more difficult. The condition of the heart must then be watched. There are cases where the heart is weary, overworked. Such cases are often associated with arterial sclerosis. The acetone odor can be noticed in the breath, marked in many cases. First syncope, followed by speedy cardiac failure. Heart disease is not so rare in these cases. The speaker cited a case of a lady aged seventy-three, recently dead. She had had the disease thirteen years. Three years ago it showed itself in weakness of the pulse—beats twenty-four to thirty, perfect bradycardia. Death was easy and painless. Her husband, a broker, aged seventy-two, developed diabetes. Lived two years.

Diabetes may be a cause of neuro-muscular disease, fatty degeneration of the heart, etc. Doubtless, the poisonous action of ptomaïnes has an important influence. Gastro-intestinal symptoms and marked dyspepsia are well known in connection with diabetes and chronic interstitial nephritis. To repeat, the heart must be watched in all cases of diabetes. The diet in such cases requires careful study.

Diabetes is more often a disease of the whole system than any special organ. Brain and heart disease, and locomotor ataxia may be found as complications.

DR. STEVEN MACKENZIE, of London, reported eighty cases; forty-five died suddenly. In the profession there is an increasing opposition to an exclusive meat diet. Adapt the therapeutic requirements to individual cases. Study all cases on their individual indications; obtain from the patient a minute history of the case. Get also full life history. There are no fixed rules for treatment. No absolute meat diet; rest and massage; try to get rid of the sugar; try the usual alkaline treatment; if soda solutions do not agree he gives opium in some cases; watches its effect on heart and stomach. Schlott's method is valuable.

In cases of diabetic coma he deemed it most important to evacuate the bowels. Then fill the lower colon with alkaline water. So far he has seen no case recover.

Chronic Heart Disease Treated by the Schott Method of Baths and Gymnastics.—DR. ROBERT H. BABCOCK, of Chicago, read a paper with this title. The baths owe their efficacy to saline and alkaline constituents, and also to their warm temperature. Warm baths, in such cases, as a rule, are debilitating. Temperature should be 92° to 93° F., gradually reduced to 87° F. They feel warm at 92° F; often chilly at 87° F. The duration of the bath is limited, one bath a day. They are omitted every fourth day. They are given during six months. After each bath the patients rest an hour, to rest the heart. Pulse is lower during the bath. Under the baths there is improvement in the rate and quality of the pulse. Sphygmographic tracings show the marked improvement in the cardiac currents. Baths lessen the rapidity and decrease the force of the heart's action.

The baths act by causing contraction of the cutaneous vessels. A cold bath is followed by a slower and stronger pulse, and by dilatation of the internal vessels. The *modus operandi* of the baths may be described as follows: First, patient may experience a sensation of chilliness, followed by warmth, due to the gentle stimulation of the cutaneous nerves caused by the salines in the bath. The bath is an aid to the heart. Baths slow and strengthen cardiac contractions. Light exercises, gymnastic movements of flexion and extension of the trunk—a skilled attendant directs them. All exercise within fatigue. No exercise is permitted that embarrasses respiration. Call a halt when there is any evidence of dyspnœa. The exercise acts on the heart and circulation in much the same way as the baths. Gymnastics slow the rate and increase the volume of the pulse. A sensation of comfort follows the bathing. Exercise improves the arterial circulation. Cases so treated receive permanent amelioration.

DR. BABCOCK reported 19 cases treated by him. Nine males, 10 females. He deems the treatment very risky in cases of aneurism and arterial sclerosis. Schott does not deem chronic interstitial nephritis as contraindicating the treatment.

DR. ROLAND G. CURTIN, of Philadelphia, referred to cases in the Philadelphia Hospital where there was temporary diabetes or saccharine urine. It was not a serious symptom and disappeared. They appeared last fall.

DR. GLENTWORTH R. BUTLER, of Brooklyn, said that the disease known as diabetes was but a symptom of some underlying condition. It may be caused by some lesion of the liver or pancreas, or the result of one of the numerous processes of metabolism. Glycosuria is the symptom. There are weak hearts in such cases. General muscular weakness in that disease, and the heart participates; degeneration of the muscular fibres of the heart. Cited a case in his practice. Man aged fifty-five. Urine showed a small percentage of sugar—one tenth of one per cent. Coma came on without any warning. Two months ago had an attack of syncope, an examination revealed dilatation of the heart. Under treatment the heart improved. Man did well, except an attack of syncope of very brief duration, brought on by over-exertion. Regarding diet in diabetes, he accepts no fixed rules. The general condition of such patients is impaired. He does not believe in cutting off all the carbohydrates and saccharine substances at once. He mentioned a case of a pregnant woman. Found lactose in the urine. It was due to irritation of the nervous system. She improved under treatment and the symptoms disappeared.

DR. CHARLES E. QUIMBY, of New York, referred to the defect in all our to day methods in treating cardiac disease. Arterial extension must be present if we are to have good circulation. In aortic regurgitant disease there is a slowing in the circulation. He thought that the indications, in the treatment of valvular lesions, was to hasten circulation and keep up the nutrition of the body.

A New and Distinguishing Sign of Latent Aneurism of the Aorta.—DR. GLASGOW, of St. Louis, Mo., said that in most cases of aneurism, early in their history there was an utter absence of dulness on percussion. That at a later period only were physical signs manifest. Then pressure symptoms, etc., gave a suspicion of the disease. He said that his new sign in thoracic aneurism is the presence of a systolic sound in the brachials—due to vibration of their walls; that it was synchronous with the systole of the heart. It is practised by having the patient extend the arm at a right angle from the body, and by placing the ear over the brachial. The vibrating sound got by the ear he designates as his new sign of aortic aneurism. He finds no mention of such a sound in the older English, French, or German classics on heart-disease and aneurism. He gave reports on five cases in his practice.

DR. MURRAY, of Washington, presented a patient whom he regarded as a "suspect." The man was a negro, aged twenty-six. Pulse, irregular; pain in the left side; pain in shoulder to wrist left side; right side, a small area of dulness; no cardiac murmur; heart apparently normal. He suspected aneurism. Dr. Glasgow had called on him; he practised Dr. Glasgow's pathognomonic sign, and found the brachial systolic sound.

Dr. Curtin, of Philadelphia, had been working in much the same direction—an earlier means for discovering aneurism. He thinks that digitalis increases the force of the heart and increases the aneurism. Had been experimenting on the effects of pressure on the chest-walls, with a view to an easier location of aneurism. Had reduced chest circumference an inch and a half; described a method of bending forward to facilitate feeling an aneurism through the supra-sternal fossa.

Ozone in Phthisis.—Dr. Charles E. Quimby, of New York City, read a paper entitled, "Ozone in Phthisis, with special reference to the Pneumatic Cabinet."

Reviewing the medical history of phthisis, tubercle bacilli, and medical agents, he said that the use of creosote may be due to the lingering belief that it acts as a germicide. Since he had made a systematic study of the disease, he wished to attack it through the systemic forces. He referred to recurrent tubercular and septic influences. For a year past his agents in treatment had been three, alcohol, creosote, and oil of cloves.

Mention was made of an apparatus devised by him fulfilling all requirements. His plans were available to anyone interested in the matter. Next he dwelt at length on the powerful oxydizing properties of ozone. It was described as stimulant. Reviewing the pathology of phthisis he said that a large number of cases were adynamic in character—a fact duly recognized by Koch. In the disease there was a degeneration and necrotic activity.

The use of the pneumatic cabinet and ozone was described. The treatment was applicable in any stage of the disease. He reported a number of cases benefited by the treatment. He makes no claim that they are cured; changes noted are due to local stimulation. Ozone is a powerful stimulant to the mucous membranes. It is a pulmonary antiseptic, an agent of known value. He does not know of any remedy that will destroy tubercle bacilli in the tissues. Effects of ozone on tubercle bacilli in sputa are nil.

The ozone treatment gives a prompt reduction in temperature. It gives a result quite equivalent of climatic influences. The value of an ozonized atmosphere in phthisis is marked. Some patients cannot take iron without headache. Several of this kind after the treatment have been able to assimilate iron. In some cases under cabinet treatment the area of respiration is restored. Believes that ozone meets the demands of the system, called it a respiratory food. It can be generated in houses.

Tuberculosis in Domestic Pets.—Professor Fröhner, of the Berlin Veterinary School, has recently made some investigations as to the prevalence of tuberculosis among small domestic animals, the results of which are as important as they are interesting. In the clinic for small animals during the last seven years, out of a total number of 70,000, only 281, or 0.4 per cent., have been found to be suffering from tuberculosis. The proportion of tuberculous dogs was as low as 0.04 per cent.; cats seem to be considerably more subject to the disease, the proportion of tuberculosis among them being one per cent. The animals most severely affected are parrots, the ratio of tuberculosis among them being twenty-five per cent., no doubt owing to imperfect acclimatization. Living as these birds mostly do in rooms constantly used by members of the family, their liability to tuberculosis makes them somewhat dangerous pets.—*British Medical Journal.*

Ascites and Resignation.—Dr. Kelley, writing in the *Cleveland Medical Gazette*, says that he recently saw a tombstone in the Bunhill Fields burying-ground, London, upon one side of which was the usual inscription of name, age, and date of death, while upon the other side was carved a clinical history reading as follows:

> In 67 months she was tap'd 66 times
> Had taken away 240 gallons of water
> Without ever repining at her case
> Or ever fearing the operation.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ROYAL MEDICAL AND CHIRURGICAL SOCIETY—CARDIAC SEQUELÆ OF INFLUENZA—PAIN IN REGION OF HEART—ACCELERATION OF BEATS—A CASE OF ACANTHOSIS NIGRICANS—SIR GEORGE HUMPHREY, F.R.S.—HEALTHY LONDON—PREVALENCE OF SMALL POX—EXTENSION IN THE PROVINCES—THE LEICESTER CRAZE—THE LOCAL PRESS—DEATHS OF PROFESSOR JOHN CLAY, W. L. UNDERHILL, DAVID TAYLOR, PROCTOR S. HUTCHINSON

London, June 20, 1894.

The concluding meeting of the Royal Medical and Chirurgical Society was held on the 12th inst, when Dr. Sansom read a paper on tachycardia and cardiac pain after influenza. He had met with 100 cases in which cardiac disturbances had followed influenza at more or less distant intervals. Of these there were 23 of pain, and 37 of tachycardia; 25 irregularity (arhythmia); 5 of bradycardia, and 10 of organic disease. The present communication dealt with the first two sections of cases. The pain experienced in the region of the heart was in some cases paroxysmal and in some resembled angina; in others it was more or less protracted. It might be intense and sudden, so that some patients fell completely unconscious. In some unconsciousness occurred paroxysmally in the absence of severe pain. There were not the associated signs of true angina pectoris. Hysteria was excluded, for several patients were men, and some typical athletes, who had been in perfect health until their attack of influenza. In the cases manifesting more constant pain the beating of the heart was often accompanied by subjective discomfort; there were sometimes tender spots in the intercostal spaces close to the sternum, with more deeply seated pain in defined situations, and in several instances symptoms of concomitant neuritis involving some of the nerves proceeding from the brachial plexus. He attributed the symptoms to a neuritis affecting some of the ganglia of the cardiac plexuses, or to a disturbance of the sensorium analogous to that in epileptiform neuralgia or in visceral neuralgia. Quinine in five grain doses, with antispasmodics, morphia sparingly and cautiously administered subcutaneously, and a course of the bromides and iodides with arsenic were recommended. Good results might follow the use of a weak continuous galvanic current from the nape of the neck to the region of the vagus. Next, as to the cases of tachycardia following influenza. It might occur immediately after the attack or after several months, and continue for long periods—at least eighteen months. In many cases the heart was very irritable, quickened action being provoked by very slight causes or occurring at intervals without assignable cause. It might be accompanied by many, or even by all, the signs of Graves's disease—a circumstance which was of interest in the question of pathology of the latter affection. The most probable initial cause was a disturbance of the vagus at its origin or in some parts of its course, whereby its controlling power over the cardiac contractions became impaired; possibly irritative lesions of the accelerator nerves of the heart, in the cord, in the course of the sympathetic filaments, or in the ganglia, might be concurring causes, and in some cases hypersecretion by the thyroid might be a subsidiary cause. In the treatment of post-influenzal tachycardia drugs seemed to be inefficacious except as modifying the associated symptoms, but the systematic use of weak continuous galvanic currents from the nape of the neck to the region of the vagus might be followed by good results.

Dr. Althaus remarked that hysteria was met with in a considerable number of men. In addition to the treatment which had been adopted, he had employed salicylate of soda with much benefit in the early stages, while later a combination of phenacetin and caffein gave ad-

mirable results. The continuous galvanic current was useful, a good effect being obtained by one milliampère. As to the cause of the tachycardia, though there might be in some a peripheral neuritis of the vagus, he thought that the cardiac and vasomotor centres in the bulb were more at fault. He had never seen vomiting in these cases, though it ought to be common in peripheral neuritis of the vagus He had seen polyuria, glycosuria, and albuminuria all follow influenza, and this latter suggested the medulla oblongata as the seat of the lesion. As to the pathology of Graves's disease, some French observers had considered it to be a neurosis which left no anatomical evidence in the nervous system, while German physicians had attributed it to perverted nutrition of the thyroid body. He himself had regarded it as an organic disease of the medulla oblongata, and he rested his conclusions on both clinical and experimental grounds. It had been shown in animals that if the restiform bodies were injured the symptoms of Graves's disease would be produced, and the results of necropsies on the human subject had revealed degenerations in different parts of the medulla. He had never seen an instance of complete recovery from Graves's disease, the mortality from which was very considerable, even as high as fifty per cent., and in some who died very suddenly the cause appeared to be a failure of the cardiac centre in the medulla. Mr. Spencer Watson asked Dr. Sansom what were the signs by which it was possible to distinguish tachycardia and heart pains due to influenza from those due to other causes; and whether any group of cardiac symptoms consecutive to epidemics of influenza had not before been seen in association with other diseases. In reply to this and questions by other speakers, Dr. Sansom said, the chain of evidence between influenza and the sequelæ seemed to be complete in his cases, and he had never observed a similar grouping of symptoms without a previous attack of influenza. He agreed that salicylate of soda was good in the early stages and in the pyrexial period, but he had been chary of pushing it on account of the liability of its producing toxic effects. Phenacetin and caffein he had found very valuable. As to the question of absolute recovery from Graves's disease, he had seen some very bad cases get absolutely well, except for an occasional outburst of emotional disturbance to which so many women were liable. As regarded the urine, he had noticed exceptionally large quantities of nitrogenous products excreted, and sometimes albuminuria. He had never seen glycosuria in post influenzal tachycardia, though he had met with it in Graves's disease. Although he had never seen a typical case of spasmodic asthma due to influenza, yet he had seen several cases of marked dyspnœa of a peculiar character often spoken of as "tachypnœa." There seemed to be a general consensus of opinion that the symptoms noted were due to changes in the central nervous system, and these changes might, he suggested, be minute hemorrhages. If these hemorrhages occurred in a region which impaired the function of the vagus, then tachycardia would result; but if they occurred lower down, bradycardia and cardiac irregularity would be produced.

At this meeting Mr. Morris showed a single woman, aged thirty-five, suffering from widely disseminated discoloration of the skin, with diffuse warty growths in various parts, which he submitted as an example of the disease called by Unna "Acanthosis nigricans." Only two similar cases had been recorded (Politzer, Janovsky). Nothing was known as to its pathology. Dr. Eddowes produced some sections taken from Politzer's case. A great deal of discoloration appeared to be due to dirt, as was the case in ichthyosis. He suggested that there was a close connection between this condition and seborrhœic eczema.

LONDON, June 30, 1894.

Sir George Humphrey has been so ill as to give considerable anxiety to his numerous friends. At his best he is not very strong, and has suffered several attacks of illness. This time a severe abdominal attack has laid him aside, and phlebitis, from which he had previously suffered, reappeared. I am glad to be able to report that during the week convalescence seems to have set in steadily. Everyone is wishing him complete recovery.

Although we make such frequent complaints of insanitary conditions and preventable diseases, it is not to be supposed that Londoners are exposed to greater dangers than other citizens. In fact, not a few of us have long been satisfied that we live in the healthiest city in the world, and our boast to this effect is just now supported by official mortality records. For a month past London mortality has been at the rate of only 16.3 per 1,000, while in Paris it has been 20.5, in Berlin 18.2, and Vienna 22.5. Even you in New York have been considerably above us, although below Paris and Vienna.

We are, however, by no means free from zymotic diseases, and the continued prevalence of small-pox is most unsatisfactory. There were fewer admissions last week to the hospitals. Still there remained 170 cases under treatment. This is 21 less than the previous week, and with fewer fresh cases reported we may anticipate a decline. But a more serious circumstance is the diffusion of this disease in the provinces. A great number of towns have now contributed their quota to the records, and although in most of them the outbreaks have been localized, the necessity of looking to our armor has been made manifest to all but the most perverse faddists. Of these Leicester has for some time been the head-quarters. In that town the local authorities have boasted of a "system" of their own and rejected vaccination. They have not, however, escaped an epidemic, and the last report of the medical officer of health for the town is a most instructive document. Its influence is, unfortunately, likely to be lessened by the determined opposition of the anti-vaccination faction, led by Mr. Biggs, a town-councillor, and a member of the sanitary committee, who seems to fancy this office qualifies him to pass judgment on medical questions; for he has not hesitated to enter into controversy with the medical officer of health and to criticise his actions with no little acerbity. Moreover, this same oracle has ventured to call in question the treatment of cases in the hospital. Such inflated self-assurance should open the eyes of his fellow-townsmen to the absurdity of being led by one whose vanity is his chief qualification for setting up his private prejudice against the views of a profession of which he has not acquired the most elementary lessons.

But a sadder spectacle than that of the self opinionated town councillor is the attitude of the local press, which has lent its influence to what I suppose it imagines to be the popular view, for it is difficult to believe that the staff of a daily paper should be completely blinded by the faddists. Statistics are thrown about in a manner that would make the real statistician aghast, and which tend to encourage the notion that "anything may be proved by figures." I have friends at Leicester who are intelligent, but the faddists at present are in the majority. There may be a rude awakening for them yet. Of course for the time the town enjoys the protection afforded by the vaccination of the adult population before the present craze existed. When mothers learn how their infants have been sacrificed to this craze there may be a wailing which the most infatuated faddists may regret to have had any share in producing.

Death, ever busy in our ranks cutting down both young and old, often gives occasion to sad notices from my pen. John Clay, of Birmingham, has passed away after a short illness, aged seventy-three. Your readers will remember how some years ago he thought he had found a remedy for some forms of cancer in chian turpentine. But he had done good work as obstetric surgeon to the hospital and professor at the Queen's College. He enjoyed, too, a large practice. On the 23d inst. Mr. W. L. Underhill, of Tipton, was buried in the local cemetery. He had passed a long and active life in the town, reaching the age of eighty. David Taylor, another veteran whose

sons are among us, died on the 16th inst., in his eighty-sixth year.

In contrast with these comes the demise of Proctor, the second son of Mr. Jonathan Hutchinson, who died this week, aged only thirty-one. His health had not been robust, and he had travelled in the colonies and the States before settling down to practice. After doing so he again broke down and gave up his London prospects and went again to Canada. For a time he improved, but eventually returned to spend his last days at home, as many another promising young practitioner has done. *Sic transit.*

THE MEDICAL OPPORTUNITIES OF PARIS.

To the Editor of the Medical Record.

Sir: A medical student, earnestly desiring to do best work in the best place, I was surprised always and often annoyed by the question universally put to me by my fellow-Americans on learning that I was pursuing my medical studies at Paris: "But why do you not do all of that in America."

It was no mere chance which decided me to prepare myself there, but a well-grounded determination after careful inquiry in regard to the advantages of the best medical schools of the United States, Great Britain, Germany, Austria, and France.

The faults of others will not form the subject of this paper, though, after detailing the preparation of a doctor of medicine here, it might subsequently be interesting to draw comparisons between this, other European, and American requirements for a medical degree. The object of this paper is merely to answer the question of my American friends by outlining the work that is required here, and also enumerating the special opportunities offered at Paris for advanced and efficient work in special branches of medical science.

The paper may have a public interest in that public attention should be drawn to the preparation that is given to medical men, the doctors to whom each family intrusts the lives of its members in times of critical illness, and to whose wisdom and efficiency implicit confidence must be given. For this the public is interested that its medical service be adequately prepared and trained.

Do we give proper attention, in the requirements of our medical schools, to insure an attendance and care that vital necessity and a public conscious of its dependence should demand?

Examine the preparatory work of the continental medical student. Study the American school in comparison. Offset the vital and casualty statistics of the two worlds, with due allowance for difference of race and climate. Then come to a conclusion founded upon positive knowledge, and not hearsay evidence or impression.

How is a doctor trained in France? What is the requirement and the signification of the degree "Docteur en Médecine" of the University of Paris?

To commence the courses of the medical school a candidate must be already provided with the degrees of "Bachelier ès Lettres" and "Bachelier ès Sciences." In short, a graduate of the high standard colleges of the United States finds himself admissible to commence his medical studies here.

The courses commence in the early part of October, and continue, with but two weeks' interruption, until the middle of August, ten months. The student follows a full and carefully compiled programme of study for four years, before becoming admissible for his final and severe examinations, three in number, but each divided into several parts. The examinations are grouped as follows. At the end of the first year's work, examinations "in course" of the first year's studies must be passed, viz chemistry, the general science, organic and inorganic, with applications to medicine; physics in like manner; zoölogy, in general, with parasitology, bacteriology, and comparative anatomy; botany, in general, and *materia medica;* histology, general and technical. Twenty months later, or half way through his third year, the student presents himself for examination in general and descriptive anatomy, with practical exercise with the cadaver and subsequent demonstration of his preparation. This is perhaps the most exacting of all examinations, on account of the minutiæ of detail and technique demanded, and covering two years' work in the dissecting rooms.

At the beginning of the fourth year the examination in physiology must be passed, and after the completion of the fourth year come the strictly medical examinations, and here lies the test of four years' work. The student presents himself the fifth October after the commencement of his medical course, for the final and conclusive series of examinations for his degree.

The first of these comprises the subjects of operative surgery, external pathology and obstetrics, with practical demonstrations, before a jury, of surgical operations. After this examination (which is called the first part of the third, lasting several weeks, with delays more or less prolonged according to the need of special preparation) the student undergoes the last part of the examination, this time on the subjects of internal pathology, or pure and general medicine.

Some time later, according to the wish of the student and his readiness in preparation, comes the fourth examination. The subjects are hygiene, legal medicine, materia medica, therapeutics, and pharmacology.

Last of all the fifth examination, and in this one all the force of the student must be called into play. The examination consists of three clinics, one in medicine, another in surgery, and the other in obstetrics, made by the student before an examining jury, selected for each specialty, each member of which designates a patient chosen at the time of examination, giving the candidate ten minutes to examine his case, but no means of book preparation or assistance other than his own knowledge and personal interrogation of the case in question. This examination is an affair of several weeks, and its successful termination lifts a burden from the student's mind. Between him and his medical degree there is now but one step—the thesis.

The thesis must be on a medical subject chosen by the student, and approved by an examining committee. To this subject are brought all results of personal observation and investigation possible for the candidate to gather and digest. Much original work and many valuable counsels of his masters are there expressed in a well-developed solution, the results of medical query and theoretical problems not before determined to scientific satisfaction. The thesis is a matter of at least six months' devoted labor, and it is not rare to find a thesis the result of several years of most exhaustive and thorough study. With the presentation, publishing, and public sustentation of his thesis, our medical man reaches his goal; and, with a hard-earned degree, finishes his student career to commence the public duty for which he is so well qualified.

At Paris one does not study medicine for the "fun of it;" nor to be called, in after life, by the high sounding name of "Doctor." The study costs too dearly for that, and by the bedside, through all those years of service for the sick and poor, one leaves the personal vanity that demands a sounding title. Nothing but earnest determination and fondness for scientific work for a chosen profession gives the courage to continue to the well-merited, but poorly recompensed end of the student's efforts.

In preparation for the examinations the student has recourse to three sources, his books, the instruction given by the medical faculty and the hospital.

For the books little need be said; the masters of all branches of the sciences are at hand, modern, complete, plentiful, varied, and not too expensive.

The medical faculty of Paris belongs to the largest university in the world, and naturally has more students by several hundred, by official statistics of last year,

than any other medical faculty. Consequently the force of instructors is very large. The faculty counts thirty-five professorial chairs which give instruction throughout the entire year. Besides countless laboratory assistants, demonstrators, professor's aids and clinical aids, the force of professors in activity the present year numbers seventy or more.

Practical laboratory work is required for the following subjects: physics, chemistry, zoölogy, botany, histology, physiology, anatomy, pathological anatomy, operative surgery, with short courses in bacteriology, pharmacology, experimental pathology, general pathology, therapeutics, obstetrics, legal medicine, and hygiene.

During the year there are delivered by the professors of the faculty, at least twelve hundred lectures and seven hundred clinics, so divided as to give three lectures a week upon each of the subjects of instruction; but for internal and external pathology, legal medicine and obstetrics, twice that amount, one lecture every day on each subject throughout the school year, is given. The clinical professors each give two clinics per week. They are numbered and assorted as follows: Medical clinics, four professors; surgical, four; obstetrical, two; mental pathology, children's diseases, skin and syphilitic diseases, diseases of the nervous system, ophthalmic and diseases of the urinary organs, each one professorial clinic.

After the books and the faculty, but not the least important, comes the hospital work of the student. For the last two years of his course he is obliged to serve in the hospital two hundred and eighty-four days of each year. Without this regular service he cannot be allowed to continue his medical course. Most of the students do much more than this and follow regularly the hospital work for four years or more.

The students at the hospitals are under the control of the physician in charge of the service, the direct supervision of the chief of the resident service, and subject to the direction of the house physician of the service in which the student is accepted as an aid. In this way a systematized grade of bedside instruction and clinical observation is maintained in all of the hospitals, while, at the same time, the student serving as an aid must do all the practical work himself as fast as he becomes well grounded in its principles.

There are in all twenty six hospitals to which the students have free access and in which they are invited to serve according to their choice. In these hospitals are fifteen thousand beds, always full. The acting surgeons and physicians of this immense organization of hospitals are the best practitioners in France, chosen by competitive examination, in a struggle where success means the only way to establish a living practice at Paris. All of these surgeons and physicians devote to the hospitals the morning of every day in the year, year after year until retired by death or age.

In the hospitals, many clinics and lessons are given in addition to those under the auspices of the faculty and already mentioned.

At present there are given no less than thirty such lessons and clinics each week. Each specialty has its masters and its own hospital service; thus enabling the student, already strong in his general medical education, to choose and pursue to best advantage his chosen specialty.

In addition to all of these advantages is another that is often appreciated. Every student of the faculty of medicine is admitted without charge to all of the courses and laboratories of La Sorbonne—*i. e.* Faculty of Sciences, Collége de France and of the Museum d'Histoire Naturelle. These three institutions give the most advanced courses of science, language, and philosophy.

At the Collége de France during my course were the famous Professors Berthelot and Schützenberger in chemistry; Brown-Séquard in medicine; Balbiani, comparative embryogeny; Ranvier, histology; Ribot, experimental psychology; Renan, the philosopher; Gaston de Paris, the philologist and so through a list of famous names that this paper has not space to enumerate.

At the Museum d' Histoire Naturelle were given the courses of Frémy, Van Tieghem, Émile Blanchard, A. Milne Edwards, DeQuatrefages and others.

The faculty of sciences at the Sorbonne includes the instruction of Poincarré, Javal, Troost, Pellat, Lippman, Friedel, and Wolf, with many others, but less interesting to the student of medical science.

There remains another source of instruction at Paris, the importance of which to the medical student demands something more than a mere mention; the "Institut Pasteur."

The "Institut Pasteur" is a name well known in America. The man whose name it bears, and his marvellous work need no heralding there. But what is not generally known is the fine opportunity offered by the institute for special students in microbiology. The establishment of the Pasteur Institute is wholly in accord with the educational policy of France—the best regardless of cost, but instruction free. In consequence, in this institute, besides the equipment and accommodation for the special end for which it is constituted—the treatment of hydrophobia—there are found six special services for instruction in microbiology.

The first is the hydrophobia treatment, under the charge of Professor Grancher; the second, general microbiology, Professor Duclaux; the third, technique of microbiology, Roux; the fourth, microbiology applied to hygiene, Chamberland; the fifth, morphological microbiology, Metchnikoff; and sixth, comparative microbiology, directed by Gameleïa. These six services, each equipped with its special laboratories and apparatus, comprise about fifty workers.

The first service, treatment of hydrophobia, comprises the work of vaccination of the bitten, by Drs. Charrin and Chantemesse, and all studies relative to the subject of hydrophobia.

In the services of general and morphological microbiology, the chief, if not the only, aim, is to study the form and functional properties of the microbe, in order to know if these functions are constant or little variable and can consequently serve to characterize distinct species; or if, on the contrary, these properties exist in condition of perpetual change, vacillating in limits too large to permit their service for other means than to form their classification in groups.

The variations of form help to determine the classification question, but are not alone sufficient to decide it, even should they be more distinctly defined than is the case. The variation of physiological properties must also be determined. This is done by the difficult study in detail of pure cultures and by means of attentively applied chemical experience to test the physiological action. The chemical side of the question belongs to the service of general microbiology. In this laboratory are employed and tanght all the methods of chemical analysis capable of serving in the study of microbes, their needs of nourishment, methods of culture, and their products of secretion and excretion.

The laboratory of microbiology applied to hygiene, similar to that of general microbiology, includes in its work all that concerns the hygienic study of air. soil, and water, and also the study and preparation of all vaccines. Mark, in passing, that had the lymph of Koch passed through this laboratory, it would, in all probability, not have been amenable to the charge of killing numerous invalids, which is now so forcibly pressed against it.

The two laboratories of comparative and technical microbiology are devoted to the study of diseases of microbic origin, the first as a laboratory of special research, the second for special instruction and training. Into this latter laboratory Dr. Roux receives the entering students in series commencing every six weeks. To them are given the notions and all technical details to render the student competent in questions of microbiology. This practical laboratory technique and study renders the student capa-

ble of entering upon the advanced work and researches of his subject. At the end of his six weeks' training he passes into the other laboratory, chosen for his intended line of work, and where his stay is limited only by his needs and his capacity.

There is a fee of admission, payable once for all, and a monthly tax, according to the expenses of the laboratory, both at a minimum. The animals necessary for experiment are furnished at one-half the market price. The instruction is free; and, more than that, the administrative council exercises the right of remitting all expenses, even for personal experiment, to such workers as may be judged worthy of this remission and thus be enabled to continue their studies without expense.

As will be seen, this institute, aside from its special aim, furnishes instruction of great importance to a medical student interested in this line of work.

With the "Institut Pasteur" closes the list of medical opportunities offered in Paris. For these opportunities my fellow-students from the United States and myself were self-exiled from home, families, and friends for a period of five or six years. For these advantages, we worked with severe determination, resolved to overcome the strangeness of a foreign tongue and endure the isolation of student life in a great and foreign city. Were we mistaken in believing Paris to possess superior advantages, or were our questioners badly informed?

William S. Magill, A.M., M.D.

4656 State Street, Chicago, Ill.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 21, 1894.

	Cases.	Deaths.
Tuberculosis	52	128
Typhoid fever	14	9
Scarlet fever	45	4
Cerebro-spinal meningitis	0	8
Measles	41	5
Diphtheria	193	41
Small-pox	4	2
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Use of Bromide of Ethyl as an Anæsthetic in France.—At a recent meeting of the Société de Chirurgie M. Segond spoke on the different methods of applying anæsthetics and their composition. He said that for the last year all his operations were done under bromide of ethyl alone or inhalations of ethyl followed by that of chloroform. When the operation was of short duration the former anæsthetic sufficed alone, but it was not so when the operation was lengthy, grave, and tedious, such as hysterectomies, laparotomies, etc. No accident had ever been witnessed out of the four hundred and forty-three cases. He always administered the anæsthetic to the patient in the dorsal decubitus, and where the bromide of ethyl alone was used he poured at first a few drops on a compress and presented it to the patient, in order to accustom him as it were to the odor of the liquid, after which a large dose was thrown on the fold, which was pressed firmly over the mouth so as to prevent all communication with the free air. In twenty seconds resolution was complete and the period of excitement was frequently wanting. Where the effect of an anæsthetic had to be kept up for some considerable time a few drops of chloroform were applied from time to time. M. Bazy said that he had tried bromide of ethyl in a certain number of cases and found it satisfactory. M. Monod gave similar testimony to the merits of bromide of ethyl, but said that at the first moments of the inhalation the patient was seized with such a terrible sensation of anguish and suffocation that the speaker preferred without hesitation using chloroform. M. Berger and several other members expressed themselves in the same sense.—*Medical Press.*

Otic Gymnastics as a Cure for Deafness.—Professor Urbantschitsch, of Vienna, has again brought his reputed new method of treatment before the Vienna Medical Society in the form of a lecture (*Medical Press*). This consists of selecting different sounds which are regularly produced at the ear of the deaf until he becomes familiar with them. The sounds should be continued five to ten minutes daily, or at least three times a week. This treatment is reputed to act like magic on the young, but is slower in operation in the aged. Much depends upon the voice, however, in awakening the perceptive power, as the high and deep tones are not equal in effect. The intervals must be filled in gradually with inter-tones. If a correct record be kept during the treatment, the right ear will probably differ from the left during the period. After the perception of speech, musical tones should be practised. Urbantschitsch has constructed a harmonica with five and a half octaves, which answers this training admirably. As to the time this treatment must be continued, no limit is fixed, different cases requiring different durations before reaction sets in. Total deafness being rare, it is considered that this treatment must affect a large number of the two hundred thousand alleged, by statistics, to be helplessly deaf in Europe. Another difficulty he pointed out in educating these unhappy patients was the mental condition. In many of these cases the mind is weak, intelligence low, and education difficult to impart even in healthy ears, hence we find children making rapid progress under treatment. The practical worth of this treatment is often questioned if it be worth the trouble, but from a mere social point there is only one answer. Since commencing his treatment in "The Landesanstalt" sixty cases have been regularly under treatment. At the beginning of the course not one could hear a sentence, six of them could hear a word, twenty-two could perceive vocal sounds, while thirty-two had a trace of hearing. To day twelve could follow sentences, sixteen words, twenty-one vocal sounds, and eleven a trace of hearing. Professor Gruber agreed with Urbantschitsch in the training of the young, but considered the time far too limited to pass a definite opinion. He recollected visiting the Israelitish deaf institution thirty years ago, where the director practised this treatment with vocal sounds, and could recall many cases of children rapidly improving. Toynbee and Hinton, in their "Handbook of Aural Disease," record many favorable results by these otitic gymnastics. He also related the case of several families who have quite recovered by this slow treatment. Professor Politzer agreed with much that had been said by Urbantschitsch, but was not so sanguine of the future results. The treatment was not new, and therefore had a longer trial both in Germany and France.

Physician to the Household of the Ameer.—Dr. Lilias Hamilton has recently gone to Kabul to serve as physician to the harem of Abdurrahman, the Ameer of Afghanistan. She is to have a personal guard of six soldiers, three of whom will accompany her whenever she ventures out upon the streets of the city. The Indian Government has sought to dissuade the young lady from what it considers her venturesome undertaking, and has warned her that she goes at her own risk, and that it disclaims all responsibility for whatever of an unpleasant nature may befall her.

Purification of Water.—Alum has been regarded as one of the best means of purifying water, but Teich has found that it has no effect upon typhoid bacilli, and that cholera germs are destroyed only after the water has been treated with alum for at least twenty four hours.

THE ETIOLOGY OF THE DEFORMITIES OCCURRING IN KNEE JOINT DISEASE.

BY A. M. PHELPS, M.D.,

NEW YORK.

PROFESSOR OF ORTHOPÆDIC SURGERY IN THE UNIVERSITY OF NEW YORK AND THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PROFESSOR OF SURGERY IN THE UNIVERSITY OF VERMONT; PRESIDENT OF THE AMERICAN ORTHOPÆDIC ASSOCIATION; SURGEON TO THE CITY HOSPITAL.

Propositions.—1. In diseases of the condyles of the femur or the head of the tibia the leg always assumes a flexed position to a greater or less extent. 2. After the limb flexes the foot rotates outward, and rotation increases with flexion. 3. In diseases *confined* to the patella the limb never flexes. 4. In disease of the synovial sac, or fibrous capsule, *anteriorly*, unattended with diseases of the condyles, cartilage, lateral, or crucial ligaments, the limb remains straight.

In diseases of the entire joint, including the cartilages, the leg always flexes, whether there is fluid present or not.

I must qualify these propositions by saying that certain pathological changes which may have taken place, may modify these deformities. But such exceptional deformities are always easily accounted for, as, for instance, that seen in Charcot's disease, or in cases attended by complete destruction of either condyle or either side of the tibia. My observations have been made in a large number of cases upon which I have operated in the Post Graduate and City Hospitals, New York City, and the Mary Fletcher Hospital, Burlington, Vt., and I found that the foregoing propositions were correct, with an occasional exception, as already noted.

Many German and English experimenters have tried to account for flexion upon the fluid hypothesis. It is true that when the knee joint is forcibly injected it will flex slightly, to give the greatest possible capacity to the capsule, but this is insufficient to explain the deformities.

Barwell does not attempt to explain them, but says (Barwell, p. 106, Wood's Library, 1881), "It is true that the flexors are probably in all limbs stronger than extensors, but in fact a mere examination will show that on the flexor side muscles are rigid, and on the opposite side flaccid. Our knowledge is as yet insufficient to account for this phenomenon."

The fluid hypothesis is wrong, why?

1. Because by far the largest per cent. of knee-joint diseases are unattended by fluid effusions. Still the same picture of deformity is seen as in those cases attended by large effusions.

2. Cases of disease, extra-capsular, located in the epiphysis of the femur, or in the head of the tibia, in which the joint was not found involved at the time of aspiration, presented the same picture of deformity.

3. Large serous effusions, from synovitis or other causes, are frequently unattended with flexion.

4. After the joint is evacuated in large effusions, the limb should again assume the straight position, but it does not.

These are the chief and valid reasons why the fluid hypothesis is incorrect.

The statement of Barwell just quoted, is incorrect. I have carefully weighed the muscles acting upon the leg, and find that the flexors weigh eight pounds and the extensors fourteen pounds in the subject examined. The quality of fibre of these muscles being equal, and other things taken into consideration, the extensors would be stronger than the flexors, in the proportion of fourteen to eight, while the limb is in the straight position, as neither group would have the advantage of leverage.

Experiments to Demonstrate the Relative Strength of Each Group.—EXPERIMENT I.—A man was strapped to a table, the popliteal space at the end of the table and leg extending over. He could sustain 136 pounds suspended from his foot. Turned on his face, the patella at the edge of the table and limb extended, he could now only sustain 36 pounds suspended from the heel.

These results correspond very closely to similar ones attained by Haughton, of Dublin. (See Haughton's "Animal Mechanics.")

EXPERIMENT II.—Subject standing, right leg flexed to right angle, he could hold suspended from heel 90 pounds. In other words, the flexor group were 55 pounds stronger when the leg was flexed than when straight.

EXPERIMENT III.—Subjects standing against bar, which crossed the legs at right angles behind at the popliteal spaces, the left toe of foot against a spike in the floor to prevent slipping. A strap around ankle of left leg adjusted to spring scales, which were pulled upon from behind, showed a resistance of the extensor group of muscles of 240 pounds.

Same subject was strapped on his back, leg hanging at right angles over the edge of the table. The same scales were now pulled upon under the table, and it was found that a pull of 80 pounds would flex the leg still further, a difference of 150 pounds of resistance in the quadriceps group of muscles between the leg flexed and extended. Then we have this formula for extensor and flexor group:

1. Flexors, first experiment, 35 pounds. Extensors, same experiment, 136 pounds. Difference of power of each operating with equal advantage, equal 90 pounds.

2. Flexors, same experiment, leg flexed, greatest advantage of flexors, 90 pounds. Extensors, leg straight, greatest possible advantage for extensors, equal 240 pounds. Experiment III. Difference, equal 150 pounds.

Difference in favor of flexor, limb straight or flexed, 55 pounds.

Difference in power of extensors, limb flexed or straight, 150 pounds. This proves that the extensors are stronger than the flexors, the proportion being 240 to 90, the limb being straight to give extensors the greatest advantage, and flexed to give the flexors a similar advantage. The limb when flexed, so modifies the strength of these groups as to make the proportion in favor of the flexors as 90 is to 80

The extensors lose in power as the limb flexes, while the flexors increase in power in about the same proportion. We all remember the futile effort of one boy to bend the other's leg by putting his knee in the popliteal space, and grasping the foot, the other boy on his face. And again, sitting on a fence while hunting, the toes under or behind a rail, one can easily lower himself backward until the head is on the ground, and can quite easily again resume the upright position. The power exerted by the quadriceps group of muscles in such a case, acting as a pulley over the end of the femur, raising a weight of 150 pounds on the end of a lever (the femora) of nearly two feet, must be enormous, amounting to hundreds of pounds.

We will now examine a knee-joint. It is a hinge

which, when in the straight position, is firmly fixed, owing to the tension of the lateral and crucial ligaments. This forces the articular surfaces firmly together and prevents lateral motion. The leg flexed, there is lateral

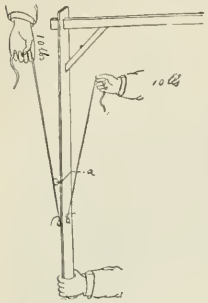

Fig. 1.

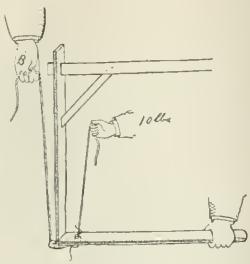

Fig. 2.

motion of the joint, which increases as the leg flexes, and not only lateral but rotary motion. This is due to the relaxation of the crucial and lateral ligaments by flexion. Another fact: the patella, and a portion of the capsular,

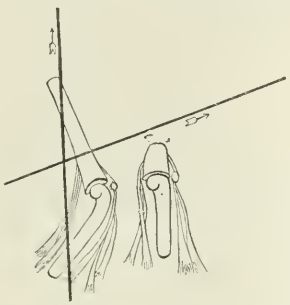

Fig. 3.

anteriorly receives its nerve-supply from the obturator, and possibly from the anterior crural. The other portion of the joint is supplied from the great sciatic. The great sciatic supplies the flexor group, while the obturator and anterior crural supply the extensor group. A clinical fact is, that when the entire joint is attacked with acute inflammation, all the muscles surrounding it are affected by spasm. Still flexion rapidly takes place, whereas disease of the condyles always produces great spasm and rapid atrophy of the flexors, while the extensors remain quiescent. Diseases limited to the patella produce spasm and atrophy of the quadriceps extensor femoris, and the limb remains straight.

Fig. 4.

Understanding that the extensors are stronger than the flexors; that the muscles about the joint are equally affected by spasm when the entire joint is diseased, why does not the leg remain straight? Before attempting to answer the question, I desire to call your attention to these diagrams. Fig. 1, a lever with a joint at *a*. Both hands pulling ten pounds, the bar would not flex. But the bar being flexed at right angle puts one string on the lever and the other around the pulley (Fig. 2). This gives to the string acting on the lever a tremendous advantage, quite easily calculated. This is exactly what takes place when the leg flexes, and explains the difference in power as illustrated by my experiments. The same mechanics applies to the anatomy of the leg, roughly represented by a rude pencilling (Fig. 3). A photograph of one of my dissections (Fig. 4) shows the biceps acting on the head of the fibula, the limb straight, and also the extensors and patella. When this leg is flexed the biceps is seen to act on a lever, and the extensors over a pulley (head of the femur). The muscles being dried, do not give an accurate idea of their position while contracted, as they fall in curves on flexion. Fig. 5. The same leg straight, showing inside flexors acting on the tibia. Fig. 6. The same leg flexed. It will be seen that these flexors increase in power as the leg flexes, by being placed on a lever, and the extensors decrease by being wound around the head of the femur.

Q. Why does the leg flex when the entire joint is diseased, and all muscles are equally affected by spasm?

A. When the leg is straight the tension upon the lateral and crucial ligaments produces great pressure between the articular cartilage. This produces great pain, and the patient to relieve this flexes the leg to relax these ligaments. This at once relieves intra articular pressure. But the flexion of the leg has put the flexors on a lever and the extensors on a pulley. The flexion now having the advantage, will continue to flex the leg.

Fig. 5.

Q. Why does the leg rotate outward?

A. Flexion, by relaxing the lateral and crucial ligaments, permits free lateral and rotary motions at the knee joint. The biceps inserted into the head of the fibula, and being the stronger of all the flexor group, and having the advantages of direction and leverage, rotates the leg outward.

Q. Why does the leg never flex in diseases of the patella alone?

A. Because the reflexes from the area of disease are transmitted through the obturator and anterior crural nerves, which supply only the quadriceps. A voluntary effort to relieve pain is also present.

Q. Why are the extensors relaxed in disease confined to the head of the tibia and condyles of the femur posteriorly?

A. The reflexes from the area of disease are transmitted through the great sciatic, which nerve supplies the flexors. Exceptional deformities are produced from pathological destruction of bone or soft parts.

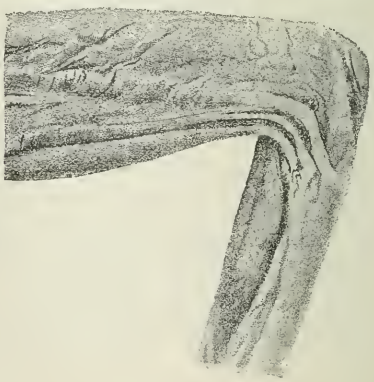

Fig. 6.

Conclusions.—Typical deformities are produced by change of leverage and action of muscles due to:

1. A voluntary effort to relieve pressure and pain.
2. Involuntary spasm and contraction of muscles, which increases the deformity by advantage of leverage due to flexion.
3. Nervous irritation of groups of muscles due to localized lesion in or about the joint.
4. Exceptional deformities are produced by pathological destruction of bone or soft parts.
5. Outward rotation of the leg is produced by spasmodic contraction of the biceps after flexion has taken place. Flexion allows lateral and rotary motion at the joint.

GENIUS AND DEGENERATION.

By JAMES WEIR, Jr., M.D.,
OWENSBORO, KY.

That the psychical function or intellectuality is frequently developed at the expense of the physical organism is well known, and that genius is seldom or never unaccompanied by physical and mental degeneration is a fact that can no longer be denied. I use the word degeneration in its broadest sense, and intend it to include all kinds of abnormalities. The facts noted above are by no means recent knowledge, but were vaguely recognized and commented on centuries and decades of centuries ago by the Hebrews and kindred races of people. The Hebrew word *nabi* means either madman or prophet, and it is now admitted that most of the prophets gave evidences of insanity as well as genius. The Greeks and the Romans recognized this kinship, and we read in the Bible of a certain Festus who, when confronted by a man of genius and being unable to answer his arguments, said to him, "Paul, much learning hath made thee mad!" Lauvergne, when speaking of the oxycephalic (sugar loaf) skull, an unquestionable example of degeneration, wrote many years ago, "This head announces the monstrous alliance of the most eminent faculty of man, genius, with the most pronounced impulses to rape, murder, and theft."

The purpose of this paper is to show that wherever genius is observed, we find it accompanied by degeneration, which is evinced by physical abnormalities or mental eccentricities. It is a strange fact, however, and one not noticed by Lombroso or any other writer, as far as I know, that mechanical geniuses, or those who, for the most part, deal with material facts, do not, as a rule, show any signs of degeneration. I have only to instance Darwin, Galileo, Edison, Watts, Rumsey, Howe, and Morse to prove the truth of this assertion. It is only the genius of æstheticism, the genius of the emotions, that is generally accompanied by unmistakable signs of degeneration. I hope to amplify this conclusion in some future paper, but lack of space forbids it at the present time.

Saul, the first king of Israel, was a man of genius and, at times, a mad man. We read that, before his coronation, he was seized with an attack of madness and joined a company of kindred eccentrics. His friends and acquaintances were, naturally, surprised and exclaimed: "Is Saul among the prophets," *i.e.*, "Has Saul become insane." Again we are told that he was suddenly seized with an attack of homicidal impulse, and tried to kill David. Before this time he had had repeated attacks of madness, which only the harp of David could control and subdue. David himself was a man whose mental equilibrium was not well established, as his history clearly indicates. He forsook his God, indulged in licentious practices, and was, withal, a very immoral man at times. At his time, the Hebrews had reached a high degree of civilization. Abstract ethics had become very much developed, and any example of great immorality occurring during this epoch is proof positive of atavism or degeneration. As I have intimated before, many of the ancient Hebrew prophets, who were unquestionably men of genius, gave evidences of insanity; notably, Jeremiah, who made a long journey to the river Euphrates, where he hid a linen girdle. He returned home, and in a few days made the same journey and found the girdle rotten and good-for-nothing; Ezekiel, who dug a hole in the wall of his house, through which he removed his household goods instead of through the door; Hosea who married a prostitute because God, so he declared, had told him so to do; and Isaiah, who stripped himself naked, and paraded up and down in sight of all the people. King Solomon, a man of pre-eminent genius, was mentally unbalanced. The "Song of Solomon" shows very clearly that he was a victim of some physical disorder, sexual in its character and origin. The poems of Anacreon are lascivious, lustful, and essentially carnal, and history informs us that he was a sexual pervert.

Swinburne's poems show clearly the mental bias of their author, who is described as being peculiar and eccentric. Many of the men of genius who have assisted in making the history of the world have been the victims of epilepsy. Julius Cæsar, military leader, statesman, politician, and author was an epileptic. Twice, on the field of battle, he was stricken down by this disorder. On one occasion, while seated at the tribune, he was unable to rise when the senators, consuls, and prætors paid him a visit of ceremony and honor. They were offended at his seeming lack of respect, and retired showing signs of anger. Cæsar returned home, stripped off his clothes, and offered his throat to be cut by anyone. He then explained his conduct to the senate, saying that he was the victim of a malady which, at times, rendered him incapable of standing. During the attacks of this disorder "he felt shocks in his limbs, became giddy, and at last lost consciousness." Molière was the victim of epilepsy; so also was Petrarch, Flaubert, Charles V., Handel, St. Paul, Peter the Great, and Dostoieffsky; Paganini, Mozart, Schiller, Alfieri, Pascal, Richelieu, Newton, and Swift were the victims of diseases epileptoid in character.

Many men of genius have suffered from spasmodic and choreic movements, notably Lenau, Montesquieu, Buffon, Dr. Johnson, Santeuil, Crébillon, Lombardini, Thomas Campbell, Carducci, Napoleon, and Socrates. Suicide, essentially a symptom of mental disorder, has hurried many a man of genius out into the unknown. The list begins with such eminent men as Zeno, Cleanthes, Dionysus, Lucan, and Stilpo, and contains the names of such immortals as Chatterton, Blount, Haydon, Clive, and David. Alcoholism and morphinism, or an uncontrollable desire for alcohol or opium in some form or other, are now recognized as evidences of degeneration. Men of genius, both in the Old World and in the new, have shown this form of degeneration. Says Lombroso: "Alexander died after having emptied ten times the goblet of Hercules, and it was, without doubt, in an alcoholic attack, while pursuing naked the infamous Thais, that he killed his dearest friend. Cæsar was often carried home on the shoulders of his soldiers. Neither Socrates, nor Seneca, nor Alcibiades, nor Cato, nor Peter the Great (nor his wife Catherine, nor his daughter Elizabeth), were remarkable for their abstinence. One recalls Horace's line '*Narratur et prisci Catonis sæpe mero caluisse virtus.*' Tiberius Nero was called by the Romans Biberius Mero. Septimius Severus and Mahomet II. succumbed to drunkenness or *delirium tremens.*"

Among the men and women of genius of the Old World, who abused the use of alcohol and opium, were Coleridge, James Thomson, Carew, Sheridan, Steele, Addison, Hoffman, Charles Lamb, Madame de Staël, Burns, Savage, Alfred de Musset, Kleist, Caracci, Jan Steen, Morland Turner (the painter), Gérard de Nerval, Hartley Coleridge, Dussek, Handel, Glück, Praga, Rovani, and the poet Somerville. This list is by no means complete, as the well-informed reader may see at a glance, yet it serves to show, however, how very often this form of degeneration makes its appearance in men of genius. In men of genius the moral sense is sometimes obtunded,

if not altogether absent. Sallust, Seneca, and Bacon were suspected felons. Rousseau, Byron, Foscolo, and Caresa were grossly immoral, while Casanova, the gifted mathematician, was a common swindler. Murat, Rousseau, Wagner, Clement, Diderot, and Praga were sexual perverts. Genius, like insanity, lives in a world of its own, hence we find few, if any, evidences of human affection in men of genius. Says Lombroso: "I have been able to observe men of genius when they had scarcely reached the age of puberty; they did not manifest the deep aversions of moral insanity, but I have noted among all a strange apathy for everything which does not concern them; as though, plunged in the hypnotic condition, they did not perceive the troubles of others, or even the most pressing needs of those who were dearest to them; if they observed them, they grew tender and at once hastened to attend them; but it was a fire of straw, soon extinguished, and it gave place to indifference and weariness."

This emotional anæsthesia is indicative of psychical atavism, and is an unmistakable evidence of degeneration. Lombroso gives a long list of the men of genius who were celibates. I will mention a few of those with whom the English-speaking world is most familiar: Kant, Newton, Pitt, Fox, Beethoven, Galileo, Descartes, Locke, Spinoza, Leibnitz, Gray, Dalton, Hume, Gibbon, Macaulay, Lamb, Bentham, Leonardo da Vinci, Copernicus, Reynolds, Handel, Mendelssohn, Meyerbeer, Schopenhauer, Camoëns, and Voltaire. La Bruyère says of the men of genius: "These men have neither ancestors nor descendants; they themselves form their entire posterity."

There is a form of mental obliquity which the French term *folie du doute*. It is characterized by an incertitude in thought co ordination, and often leads its victims into the perpetration of nonsensical and useless acts. Men of genius are very frequently afflicted with this form of mental disorder. Dr. Johnson, who was a sufferer from *folie du doute*, had to touch every post he passed. If he missed one, he had to retrace his steps and touch it. Again, if he started out of a door on the wrong foot, he would return and make another attempt, starting out on the foot which he considered the correct one to use. Napoleon counted and added up the rows of windows in every street through which he passed. A celebrated statesman, who is a personal friend of the writer, can never bear to place his feet on a crack in the pavement or floor. When walking, he will carefully step over and beyond all cracks or crevices. This idiosyncrasy annoys him greatly, but the impulse is imperative, and he cannot resist it. Those who have been intimately associated with men of genius have noticed that they are very frequently amnesic or "absent-minded." Newton once tried to stuff his niece's finger into the bowl of his pipe, and Rovelle would lecture on some subject for hours at a time, and then conclude by saying: "But this is one of my arcana which I tell to no one." One of his students would then whisper what he had just said into his ear, and Rovelle would believe that his pupil "had discovered the arcanum by his own sagacity, and would beg him not to divulge what he himself had just told to two hundred persons."

Lombroso has combed history, as it were, with a fine-tooth comb, and very few geniuses have escaped his notice. This paper, so far, is hardly more than a review of his extraordinary, comprehensive work; therefore, I will conclude this portion of it with a list of men of genius, their professions, and their evidences of degeneration, as gathered from his book:

Carlo Dolce, painter, *religious monomania.*
Bacon, philosopher, *megalomania, moral anæsthesia.*
Balzac, writer, *marked epilepsy, megalomania.*
Cæsar, soldier, writer, *epilepsy.*
Beethoven, musician, *amnesia, melancholia.*
Cowper, writer, *melancholia.*
Chateaubriand, writer, *chorea.*
Alexander the Great, soldier, *alcoholism.*
Molière, dramatist, *epilepsy.*
Charles Lamb, writer, *alcoholism, acute mania, melancholia.*
Mozart, musician, *epilepsy, hallucinations.*
Heine, writer, *melancholia, spinal disease.*
Dr. Johnson, writer, *chorea.*
Malibran, *epilepsy.*
Newton, philosopher, *amnesia.*
Cavour, statesman, philosopher, *suicidal impulse.*
Ampère, mathematician, *amnesia.*
Thomas Campbell, writer, *chorea.*
Blake, painter, *hallucinations.*
Chopin, musician, *melancholia.*
Coleridge, writer, *alcoholism, morphinism.*
Donizetti, musician, *moral anæsthesia.*
Lenau, writer, *melancholia.*
Mahomet, theologian, *epilepsy.*
Manzoni, statesman, *folie du doute.*
Haller, writer, *hallucinations.*
Dupuytren, surgeon, *suicidal impulse.*
Paganini, musician, *epilepsy.*
Handel, musician, *epilepsy.*
Schiller, writer, *epilepsy.*
Richelieu, statesman, *epilepsy.*
Praga, writer, *alcoholism.*
Tasso, writer, *alcoholism, melancholia.*
Savonarola, theologian, *hallucinations.*
Luther, theologian, *hallucinations.*
Schopenhauer, philosopher, *melancholia, omniphobia.*
Gogol, writer, *melancholia, tabes dorsalis.*
Lazaretti, theologian, *hallucinations.*
Mallarmé, writer, *suicidal impulse.*
Dostoieffsky, writer, *epilepsy.*
Napoleon, soldier, statesman, *folie du doute, pseudo-epilepsy.*
Comte, philosopher, *hallucinations.*
Pascal, philosopher, *epilepsy.*
Poushkin, writer, *megalomania.*
Renan, philosopher, *folie du doute.*
Swift, writer, *paresis.*
Socrates, philosopher, *chorea.*
Schumann, musician, *paresis.*

Bunyan, writer, *hallucinations.*
Swedenborg, theologian, *hallucinations.*
Loyola, theologian, *hallucinations.*
J. S. Mill, writer, *suicidal impulse.*
Linnæus, botanist, *paresis.*

The reader will observe that I have made use of the comprehensive word, writer, to designate all kinds of literary work except theology and philosophy. The above list is by no means complete, and only contains the names of those geniuses with whom the world is well acquainted. When we come to the geniuses of the New World, we find that they are few in number, and that they likewise show erraticism and degeneration. Poe was undoubtedly a man of great genius, and his degeneration was indicated by his alcoholism. Aaron Burr was the victim of moral anæsthesia, and Jefferson was pseudo epileptic and neurasthenic. Randolph was a man of marked eccentricity, and Benedict Arnold was, morally, anæsthetic. Henry Clay was addicted to an overindulgence in alcohol; likewise Thomas Marshall and the elder Booth. Booth also had attacks of acute mania. His son Edwin had paresis, so also had John McCulloch, John T. Raymond, and Bartley Campbell. A distinguished statesman and politician, and a man who stands high in the councils of the nation, has, for a number of years, given evidence of mental obliquity, by his uncontrollable desire for alcohol No power, outside of bodily restraint, can control him and keep him from indulging his appetite for alcohol when this desire seizes him. One of the most noted poets of to-day, whose verses stir the heart with their pathos and bring smiles to the gravest countenances with their humor, was, for a number of years, an inordinate user of alcohol. Robert Ingersoll is undoubtedly a man of genius and of considerable origi-

nality, and a close study of his writings shows conclusively his mental eccentricity. Judging wholly from his printed utterances, Mr. Ingersoll is only a superficial scientist and mediocre scholar. His power lies in his wonderful word imagery, and his intricately constructed verbal arabesques. He is a verbal symbolist. Symbolism, whenever found, and in whatever art, if carried to any extent, must necessarily be an evidence of atavism, consequently of degeneration.

Thomas Paine gave evidences of a lack of mental equipoise. We find scattered throughout his works the most brilliant, irrefutable, and logical truths side by side with the most inane, illogical, and stolid crudities. Among other men of genius who showed signs of degeneration we may include Alexander Stevens, Joel Hart, Adams, Train, Breckenridge, Webster, Blaine, Van Buren, Houston, Grant, Hawthorne, Bartholow, Walt Whitman. We must not confound genius and talent—the two are widely different. Genius is essentially original and spontaneous, while talent is to some extent acquired. Genius is an abnormality, but one for which the world should be devoutly grateful. Psychos, in the case of genius, is not uniformly developed, one part, being more favored than the others, absorbs and uses more than its share of that element, whatsoever it be, which goes to make up intellectuality, hence the less favored or less acquisitive parts show degeneration. Why genius should exist is one of the unexplained phenomena of nature, but that it is the result of natural causes I have not the slightest doubt.

Movable Liver.—Dr. Leube remarks on the rarity of this condition. The ligaments attaching the liver to the diaphragm must become loosened. (*The British Medical Journal.*) Pendulous belly due to repeated pregnancies, chronic ascites, etc., predispose. He records a case in a lad, aged seventeen, with heart disease and general dropsy. The abdomen had to be tapped, a fine trocar being used, and ten, sixteen, and ten litres were drawn off at different times. On admission the umbilicus bulged, a fluctuation thrill could be easily felt, and the abdomen was dull all over, except in the region of the stomach. The liver reached 10 ctm. below the ribs in the mammary line; the surface was smooth, the consistency hard, and the organs pulsating. Behind, pulmonary resonance extended on both sides down to the eleventh vertebra. After tapping, a depression was noted in the upper part of the right abdomen, and lower down a projection. This tumor measured ten to eleven ctm. in the middle line, and 15 ctm. in the right mammary line, and over it the percussion note was dull. The lower border could be followed from left to right, and the convex upper surface of the liver felt. Between the liver and the diaphragm fluctuation could be made out, and the surface of the liver could be dipped upon. The liver could be readily pushed up, the pulmonary resonance behind being then raised 1 ctm. The fluid seemed to remain between the liver and the diaphragm, whether the patient was lying down or sitting up. This was also proved at the necropsy, the lad dying some months later. The liver was very movable, enlarged, and of the nutmeg variety, with consequent induration. The suspensory ligament was 7½ ctm. long. The pulmonary resonance behind was raised when the liver was pushed up, owing to the displacement of the fluid backward. An additional cause of the mobility of the liver may lie in the loosening of its posterior attachment, for usually the vena cava is firmly bound with the liver and vertebral column. This case, as well as another seen by the author, occurred in men; hitherto movable liver has been exclusively seen in women.

Tubercle Bacilli.—Dr. Krönig succeeded recently in finding tubercle bacilli in the blood, taken from the heart post mortem of a case of acute miliary tuberculosis, by means of centrifugal motion. He thinks the method would also succeed with blood taken during life.

PASTEURIZED MILK AS SUPPLIED TO THE POOR BY THE STRAUS MILK DEPOT OF NEW YORK.[1]

By ROWLAND GODFREY FREEMAN, M.D.,

PATHOLOGIST TO THE FOUNDLING HOSPITAL; PATHOLOGIST TO ST. MARY'S FREE HOSPITAL FOR CHILDREN; ASSISTANT PHYSICIAN TO ROOSEVELT HOSPITAL, OUT-PATIENT DEPARTMENT.

It is the purpose of the writer to describe some of the details of a most worthy charity, the expenses of which have been met by one man, since perhaps other equally charitable persons here or in other parts may be disposed to carry out the same sort of work, and may thus be able to benefit by the methods here described.

Since there can be no doubt that the milk supply may be a source of danger on account of the large number, and possible pathogenic character, of the micro organisms contained in it, it becomes of the greatest importance to investigate the manner of this contamination and the methods of avoiding its dangers. The most important source of contamination is undoubtedly the dairy, where dirty and ignorant methods are almost universally employed, not only during the milking but in the subsequent care of the milk. Delay in transportation affords time for the multiplication of the germs which have entered the milk.

It is evident that this danger may be met in one of two ways: best by a reformation in dairy methods and the manner of transportation, but failing in this, by sterilization. It is the object of this paper to show how this latter has been accomplished on a large scale in New York, for the purpose of supplying milk to the poor.

As such an undertaking is original and certainly worthy of emulation, and at the same time of great service to those members of the profession who practise among the poor, it may be of interest to know how the work was done and what the results were.

This enterprise is due to the philanthropy of Mr. Nathan Straus, who, in the spring of 1893, established and has since maintained a depot for supplying the poor with a good quality of raw and sterilized milk. His first aim was to obtain as pure a milk supply as possible, and for this purpose the dairy was inspected by Mr. S. K. Johnson, veterinarian of the New York Board of Health, and was approved by him. The depot in New York has been admirably planned and superintended by Mr. A. L. Kinkead. Three sorts of milk were provided: pasteurized ordinary milk, pasteurized modified milk, and raw milk.

Pasteurization at about 75° C. (167° F.) was used instead of sterilization at 100° C. (212° F.), under the assumption that it furnishes a more nutritious and more digestible milk than that sterilized at a higher temperature, and at the same time one which is freed from deleterious germs. Pasteurized ordinary milk was sold in eight-ounce bottles at one and a half cent each.

The pasteurized modified milk is simply a one-half dilution of ordinary milk with the addition of sufficient sugar of milk to bring up the amount in the dilution to five per cent., and enough lime-water to neutralize any slight acidity the milk might have, and then the mixture is pasteurized.

In this way a milk approximating somewhat mothers' milk is furnished. The formula used is:

Sugar of milk	12 oz.
Lime-water	8 oz.
Milk	1 gal.
Water	1 gal.

It is evident that the deficiency in this dilution is in fat. It was intended, however, for very young or sick infants, and for these answered very well. On the other hand, to have increased the fats would have introduced some difficulties. This pasteurized modified milk is dispensed in six-ounce bottles, a charge of 1½ cent being made for each bottle. With each six or eight-ounce bottle of milk a sterile nipple is supplied. A deposit is re-

[1] Read before the Section of Pediatrics of the New York Academy of Medicine on May 10, 1894.

quired of 2½ cents for each six-ounce bottle and nipple, and 3 cents for each eight-ounce bottle and nipple. It was thus intended to furnish for infants and sick children a sterile milk of good quality in a sterile nursing-bottle, with a sterile nipple through which it could be fed.

This milk depot was located on a pier at the foot of East Third Street, that situation being accessible to a very large tenement-house population. Awnings and seats were put up on the pier so that the babies and their mothers could remain there and inhale the fresh air from the river.

The building which was erected was, owing to the character of the site, of necessity long and narrow; it was placed several feet from the edge of the pier, so that an outside passageway connecting the rooms was reserved. The building was divided into four rooms. The first room is used for sterilizing the bottles, stoppers, and nipples, and preparing and pasteurizing the milk. The second room is occupied by large water-baths of iced water for keeping the pasteurized milk until it is delivered. The third room contains ice-boxes for the cans of raw milk. The fourth room, which is nearest the end of the pier, is devoted to the business of selling the milk.

The first of these rooms contains all the apparatus: the ovens for sterilizing the bottles at a dry heat of 150° C. (302° F.), the mixer used for the preparation of the modified milk, the pasteurizers, and the trough of running water for rapid cooling after pasteurization. This room has a slanting cement floor which can be flushed with a hose for purposes of cleanliness. The ovens for sterilizing the bottles are made of sheet iron and heated by gas. The bottles, after being thoroughly cleansed, are placed in this oven, which is then closed and the gas beneath is lighted. The bottles are kept here at a temperature of 150° C. (302° F.) for one hour. The bottles used were especially designed and made for the purpose. They have sloping necks so as to be easy to clean, and spheroidal bottoms so that they will not stand up. This latter peculiarity was introduced so that they might not be opened and left standing uncorked, thus allowing a further contamination of the milk by bacteria.

The method of pasteurization used is the same as that applied by me to the small apparatus which I described two years ago.[1] The principle is as follows: If into a definite amount of boiling water, the source of heat having been removed, a properly proportioned amount of cold milk be introduced in bottles under such conditions that they will not break, the temperature of the milk will be raised to the desired point, *i.e.*, 75° C. (167° F.). The amount of boiling water used in this apparatus is such that, in raising the temperature of the milk through about 60° C. (108° F.) it itself loses an equivalent amount of heat, so that when the milk reaches its maximum temperature the water is of the same temperature.

The apparatus used at the Straus depot consists of large copper boilers for the water, and copper receptacles for the bottles of milk. The boilers are twenty-four inches long and have a groove encircling them, to indicate the point to which they are to be filled with water. The receptacles consist of groups of copper cylinders, each one just large enough to contain one bottle. These receptacles are made of different sizes for six-ounce, eight-ounce, or pint bottles. The apparatus is thus essentially the same as the small apparatus referred to above, except that it is of larger size, allowing a greater number of bottles to be pasteurized at a time.

The method of pasteurizing the milk is as follows: The boilers are first filled with water to the groove and the gas stoves beneath them are lighted. The sterilized bottles, having been cooled, are now filled with milk and loosely stoppered with rubber corks which have previously been sterilized in boiling water. The stoppered bottles are then placed in the hollow copper cylinders of the receptacles, and the space surrounding the body of the bottle in each cylinder is filled with cold water. As they are prepared, they are left on a shelf until the water in the boilers generates steam vigorously, indicating a temperature of 100° C. (212° F.). The gas under the boilers is then turned off, and the receptacles containing the filled bottles are set in the boiling water; the boilers are then covered and not disturbed for half an hour. The milk here reaches a temperature of about 75° C. (167° F.) in ten minutes, and remains at that temperature for the remaining twenty minutes. The receptacles containing the bottles are then removed and placed in the tank of running water for twenty minutes, at the end of which period the milk in the bottles has reached nearly the temperature of the surrounding water, that is, 20°–25° C. (68°–77° F.). They are then carried into the next room, where the bottles are removed and placed in racks in iced water at a temperature of about 10° C. (50° F.). They are kept here until dispensed. Sufficient milk for one day's use is pasteurized, and it is never carried over.

As soon as one lot of receptacles is taken from a boiler, the gas beneath is lighted, and the temperature of the contained water, now about 75° C. (167° F.), is brought to boiling for a new lot of receptacles, which, with their bottles, are at once introduced.

A large number of experiments with milk subjected to this treatment, show that by it the practical purposes of sterilization are accomplished. With each bottle of milk a rubber nipple is supplied which has been sterilized in boiling water.

Of this pasteurized milk twenty-five hundred bottles were dispensed in a single week, and thirty-four thousand bottles were supplied during the season. Five persons were employed in this depot during the summer of 1893, including a cashier, a porter, and a scrubwoman. The actual technical work of pasteurizing was accomplished, for the most part, by one man. Many remarkable cases were observed of infants and children with bad surrounding, and suffering from severe gastro-intestinal disorders, who rapidly improved and attained good health on simply a good sterile food and the fresh air of the pier. It is interesting to note that, although this milk was often kept in hot tenement-houses where ice could not be afforded, only one case of the pasteurized milk turning sour was reported. This case was investigated, and it was found that the milk had been kept under the kitchen stove.

The scope and technical facilities of this charity will be enlarged this year. Six depots in various parts of the city will be established. The milk will be brought from Delaware County, N. Y., the herd supplying it being first carefully inspected by a veterinarian of the Board of Health. Both raw and sterilized milk will be supplied. The same formula will be used for the modified milk, which will be dispensed in six ounce bottles. Pasteurized milk will be sold in eight-ounce and sixteen-ounce bottles.

In addition to pasteurized ordinary milk and pasteurized modified milk, as supplied last year, a pasteurized milk diluted with barley water and sweetened with cane sugar, and containing also table salt, has been introduced at the suggestion of Dr. Jacobi. The formula used is:

Table salt	½ oz.
White cane sugar	10 oz.
Milk	1 gal.
Water	1 gal.

This barley milk will be dispensed in six-ounce bottles.

This depot will be prepared to supply hospitals and dispensaries.

205 West Fifty-seventh Street.

[1] On the Sterilization of Milk at Low Temperature, etc, MEDICAL RECORD, July 2, 1892.

He Swallowed Two Hundred Nails.—Gastrotomy was recently performed on an inmate of the Lancaster County (England) Lunatic Asylum, and nearly two hundred nails from one and a half to three inches in length were removed from the sorely overweighted stomach.

SOME ABNORMAL CONDITIONS OF THE GENERATIVE ORGANS, ASSOCIATED WITH MELANCHOLIA OR MANIA [1]

By W. GILL WYLIE, M.D.,

NEW YORK.

It is a generally recognized fact that abnormal conditions of the generative organs in women cause reflex disturbances to the nervous system, such as severe headaches, hysteria, etc.; but the fact that a chronic subinvoluted, or an enlarged and congested condition of the uterus, may induce a typical case of melancholia in some women, has not yet been fully accepted by the profession. There may be an abnormal condition of the nervous system present, and the uterine disease merely makes it active, for in many of my cases other members of the family have been mentally unbalanced, and several times I have had two sisters with the same symptoms. Even though there may be a strong predisposing cause in many cases, curing the local condition relieves all the symptoms. Most of my cases have been in women who have borne children, but in several instances I have cured well marked cases of what such men as Spitzka, Eroy, and Sachs have diagnosed as cases of melancholia, by amputating a diseased cervix uteri where diseased glands and follicles had kept up an enlarged and congested condition of the uterus in virgins. Some of these cases complained of no local pain, and a profuse leucorrhœa was the only indication of uterine disease, although most of such cases have dysmenorrhœa, backache, etc., due to the local disease, and as a rule the nervous symptoms would be classed as hysterical rather than melancholic. In three of the cases brought to me having marked delusions or acute outbreaks of mania, treatment of the uterus failed to relieve them. In one I could plainly define acute salpingitis and ovaritis, and removal of the appendages cured the mania. In the second case I could not define, even under ether, any disease of the appendages, but Dr. Spitzka said in his opinion the mental trouble was reflex, and I made an exploratory incision and found both Fallopian tubes occluded and the distal ends filled and enlarged with pus. The patient made a complete recovery, although for many weeks a trained attendant was with her night and day to prevent suicide before the last operation. The third case had well-pronounced melancholia, and I found a diseased cervix and subinvolution; this was treated in the usual way and for several months she seemed well, but then all symptoms returned. I pronounced the condition of uterus normal and proposed an exploratory incision, as she had some local pain on the sides, but on account of cost for operation, etc., she returned home, and later Dr. Van de Walker, of Syracuse, N. Y., operated and found salpingitis. The patient was reported cured.

The three cases reported to-night are those that have been recently under my care, and were all examined by well-known alienists. One well marked case of melancholia, with decided outbreaks of mania, was sent to me. Although she had a lacerated cervix uteri and some enlargement, it was not enough to account for the melancholia; so I turned her over to Dr. L. C. Gray, and he treated her as he liked for a year or more; but she was not cured, and then I operated under ether for the laceration, etc.; the effect on the mental condition was negative, but certainly did not make her worse, and I turned her over again to Dr. Gray. Without a single exception, all my cases were in every instance seen in consultation and examined by at least one alienist of good standing, and I am sure that some of the many cases of melancholia treated by opium, rest, etc., could be relieved, if not permanently and radically cured, if a gynecologist was called in consultation. I know that most doctors think they can examine and diagnose any serious disease of the uterus and appendages; but unfortunately many of them are merely unconscious of their ignorance, for all learned doctors are not artists, their brains may be great but their hands are not so well trained.

[1] Read before the Northwestern Medical and Surgical Society March, 1894.

Case I.—Mrs. S——, aged thirty-five, came to consult me, November 20, 1893. She said she had had six children; the last four years ago. After the third child was born she had some unusual nervous symptoms, but they passed off after a month or more. Since the birth of the last child she had not been well, had become very nervous, and had been treated for more than two years for nervous prostration. She imagined her husband did not like her, or that she did not love him, and everything was wrong; and at times she was so depressed that she was afraid she would kill herself. She had recently been treated by Dr. Baruch with baths, etc., and was improved in her general health. She looked in fair general health, her color was good. She had no actual pain anywhere, and had never had a local examination since the birth of her last child. After hearing her story I suggested that all her nervous symptoms might be due to subinvolution of the uterus, and she consented to an examination. I found a large and soft uterus held back in the pelvis by a very hard tumor about the size and the shape of a large kidney; it seemed to lay between the bladder or pubic bone and the uterus, but did not seem firmly attached. She gave a history of excessive menstruation, but no other direct symptoms of local disease.

I advised consultation with Dr. Sachs, he pronounced it a well-marked case of melancholia, and wished to give her treatment and keep her under observation for a week or two. Although I was told afterward that several of her family had had mental disease, I advised removal of the tumor and treatment for the subinvoluted uterus. She was admitted to my sanitarium December 1st, and Dr. Sachs began the orthodox opium treatment for melancholia; under this she was less nervous, but not relieved of her depressing thoughts.

December 11th, I operated and removed this most unusual tumor, which appeared to be a fibroid, detached entirely from the uterus and appendages, rolled up in the lower end of the omentum, and coated over with a calcareous shell. The tumor has no blood-vessels running into it and seems to have been treated by the surrounding tissues as a foreign body. It is shaped something like an abnormally large kidney; it was removed without difficulty and the patient made a good recovery. In less than two weeks patient was practically well. The uterus and subinvoluted pelvic tissues were further treated by the applications of boro-glyceride cotton pledgets put in the vagina twice a week; in six weeks patient was dismissed cured; no medicine except laxatives used after operation.

Case II.—Mrs. K——, aged thirty, was brought to my sanitarium by her father and brother, who were both physicians. In the fall of 1892 Dr. W., the brother, wrote me that his sister had been insane for four years, and for the past seven months she had been under the care of Dr. Stern, of Hartford, Conn., and seemed to be practically incurable, and wanted to know if I would take out her ovaries, as he believed that their disease caused the insanity. I wrote him that I would be glad to see the case, but I would not agree to remove the ovaries unless I could make out by local examination positive indications of actual disease of the ovaries.

December 28, 1892, I examined her. She had had four children. Four hours previous to birth of last child she had been well. Except for a time after birth of second child, she was very nervous and mentally much disturbed. The last labor was not difficult nor unusual in any way, but several weeks after labor she grew more nervous, and marked symptoms of melancholia came on, which in spite of treatment, rest, etc., gradually grew worse. Dr. Spitzka saw her and pronounced it a case of melancholia. For the past seven months she had been confined to Dr. Stern's sanitarium and was considered insane. She had a dislike for and was suspicious of her husband and family, and would get excited and rattle off a mixture of German and English that no one could understand for hours at a time. She was pale and thin,

but not in very bad general health. She needed constant care and watching by a nurse. She had been examined locally by Dr. Stern, but local treatment was not deemed necessary. On local examination I found a large, soft uterus, with marked relaxation and subinvolution of the vagina and pelvic blood-vessels. The uterus was fully as large as at two months' pregnancy, and the cervix was greatly enlarged and everted by diseased glands and follicles, and was lacerated to some extent. There was a history of excessive menstrual flow.

It was, in my opinion, a typical case of subinvolution, due to disease of the glands and follicles of the cervix, with some laceration of the cervix at labor.

Dr. Spitzka saw her and advised me to try the local treatment and operation to cure the subinvolution, etc., after regulating her bowels and feeding her carefully, and applying cotton pledgets to the vagina, soaked in sol. boro glyceride, twice a week.

On January 9, 1893, she was etherized and I dilated the uterus, curetted it, and amputated the diseased tissue of the cervix and sewed up the laceration, lining the cervical canal with flaps of healthy mucous membrane drawn in from the vaginal part of the cervix. I also dilated the anus and tied off some hæmorrhoids. For several days after the operation she was in an excited state, gabbling her jargon most of the time as she had done at intervals before, but on the tenth day she seemed to be perfectly rational and remained so without interruption. Gradually her general condition improved, and after the tenth day I made the boro glyceride applications to the vagina twice a week to hasten involution.

On January 31st she was discharged as cured, and went to her home in Brooklyn. For several weeks she came for the simple local treatment twice a week. Her menses became normal in amount and were regular till last fall, when she went over two weeks and then menstruated quite freely. Some of her old mental confusion returned, but after four or five boro glyceride applications to the vagina she felt well. She has gained flesh and strength, and attends to all her duties at home without trouble.

Case III.—Mrs. B——, aged thirty-two, admitted November 16th, said she had been married eight years, was always nervous, and several of her family had had serious mental symptoms. As a rule, she had enjoyed good health. She had had two children, and after the first child had severe pains in her head and was depressed, etc.; this gradually passed off. Eighteen months ago she had a miscarriage, since then she had some dragging sensation about the pelvis, and had gradually become very nervous and suffered, especially about the time of her menses, with severe occipital headaches, and could not help looking at this in a depressed and abnormal way. She was seen by Dr. Spitzka, who said it was melancholia, probably caused by reflex disturbance due to disease of the generative organs. Local examination revealed a large and soft uterus which bled to the touch of the sound on the endometrium. There was follicular disease of the cervix with a slight tear, and there was subinvolution of the vagina, and a laceration of the inner part of the perinæum which caused the lower end of the rectum to crowd forward the posterior wall of the vagina and form a rectocele.

November 20, 1893.—The uterus was dilated, curetted, and the diseased tissue of the cervix removed, and laceration sewed up. The perineum was also repaired and the anus dilated and treated.

The patient made a good even recovery, and after the use of the boro glyceride cotton pledgets twice a week she was dismissed cured. Once since then some of her nervous symptoms returned, but they promptly disappeared after three applications had been made of the boro-glyceride. I do not mean that the enlarged condition of the uterus which we call subinvolution, or the other diseased local conditions, will cause melancholia in all, or even in many women, but will do so in some cases, and that the melancholia seems incurable as long as the local disease remains uncured.

Clinical Department.

A CASE OF FACE PRESENTATION, WITH ROTATION INTO THE SACRAL CAVITY.

By JAMES B. BULLITT, M.D.,

GLOBE, A. T.

Mrs. N——, aged twenty-one, had previously given birth to two healthy, living children, first becoming a mother when seventeen years of age. During the third month of this third pregnancy she was threatened with an abortion; in addition to the pains, a considerable amount of bloody mucus was discharged, and the mouth of the womb was sufficiently patulous to admit the tip of the index finger. With the recumbent position and opiates the disaster was averted and she carried the child successfully until the end of the eighth month. At this time I was again called to see her; I found her in considerable pain, of intermitting type, referred to the lower portion of the abdomen chiefly, and complaining of great aching pains in the small of the back. Palpation disclosed the child's body in the first position, head presenting. The mouth of the womb was sufficiently patulous to admit the finger, which could feel the presenting head. There was a slight discharge of bloody mucus. I supposed this to be the beginning of labor, and left instructions to be sent for as soon as true pains began. The next morning, however, the condition was much the same; no true pains had commenced, and the discharge of bloody mucus had ceased. Five days later, on Friday, I was again called to see the case; true labor pains had begun the evening before, and the amniotic fluid had been discharged on Friday at two o'clock, it being six o'clock when I arrived. Pains were recurring at intervals of five minutes, and were strong, but no advancement seemed to be made. The mouth of the uterus was not more open than at the examination, five days before, just admitting the tip of the index finger. Gentle manipulation permitted the introduction of two fingers, upon which a diagnosis of face presentation with rotation posteriorly was made. The fingers received the sensation of the pelvis being bridged across, instead of being filled in with the round occiput as in ordinary occipital presentations. Under chloroform, and with the assistance of Drs. Collins and Fox, the uterine mouth was manually dilated; and then, with the hand in the vagina, two fingers on the supra-maxillary bones, and thumb on the brow, I made pressure upward, the other hand on the abdomen, pulling the head in the same direction. The head was readily dislodged; the external hand then pushed the occiput downward, the hand in the vagina pushing the chin still farther upward.[1] Conversion into an occipital presentation was readily effected; forceps were then applied, and a living child brought to the light in a short space of time. The whole procedure consumed an hour and ten minutes' time. The patient took chloroform very badly, rendering the manipulation more difficult and more lengthy than there was necessity for. The mother made an absolutely uneventful recovery; the temperature was never higher than 99° F., and in three weeks' time she was able to attend to her household duties. The child was a well developed girl, weighing seven and one-half pounds. There was a marked facial paralysis; this has gradually disappeared, leaving the child as sound as the fondest mother could desire.

The child's head was of an average size, not very small, while the mother's pelvis was also of average dimensions, not very roomy. In case of failure to carry the head upward and then convert the position into an occipital one, I should have attempted rotation of the face forward. Had this failed I was prepared to do a symphyseotomy, believing thereby it would have been an easy matter to slip the occiput beneath the pubic arch, from which point delivery would be plain sailing. Has the operation of sym-

[1] Manipulation described by Parry. American Journal of Obstetrics, May, 1875.

physeotomy been so employed? So far as I know there has been no report of such a case, but it would be unquestionably feasible. With the forceps and without symphyseotomy, the chin has been dragged down over the sacrum and perinæum, when the occiput and calvarium glided underneath the pubes.[1] Such procedure is certainly of very violent nature, and fraught with danger to both mother and child.

A CASE OF LOOSE CARTILAGE IN THE KNEE-JOINT.

By CHARLES G. R. JENNINGS, M.D.,
ELMIRA, N. Y.

Mr. A. B. G——, civil engineer, gave a history of trouble with his knee, dating back several years to an injury received in foot-ball at college. From that time he had repeated attacks of synovitis. During one of these, while examining his knee I discovered a floating cartilage on the inner side of the joint, which immediately escaped from beneath my finger and could not be found again. For nearly a year after that he was comparatively free from trouble with the knee. The cartilage reappeared unexpectedly one day while he was descending a flight of stairs, and as a result of its becoming pinched between the bones he almost fell headlong. As soon as he recovered from the shock of pain and surprise, he clapped his hand upon the knee and felt the foreign body. From that time on it made its appearance repeatedly at short intervals. It seemed to enjoy the freedom of the whole synovial sac. Wherever the sac extended, this wandering body was liable to go, sometimes being felt behind the knee in the popliteal region, sometimes above the knee beneath the quadriceps extensor, at other times below the patella, but most frequently on either side of the joint. The patient finally came to me for operation.

I doubted whether it would be possible to fix the cartilage in an accessible part of the capsule and keep it there long enough to administer an anæsthetic and prepare for a formal operation, so I resorted to the following plan of procedure: First I had the knee shaved and thoroughly scrubbed with green soap and washed with ether and sublimate; then a full antiseptic dressing was put on. The patient was allowed to go where he pleased, but was advised, whenever the cartilage made its appearance, to keep it in sight if possible until I could be notified and remove it. In a few days it got pinched again, slipped to the inner side of the joint, and there he held it until I was ready for the operation.

With my left thumb I crowded it as far down over the head of the tibia as possible and on the inner aspect of the joint. The sac seemed very loose and large, so that the body felt as if it were at the top of a well, with a strong tendency to fall back into the cavity. Cocaine was injected beneath the skin in the line of incision. Then, while pressing my thumb between the cartilage and the general synovial cavity, thus completely shutting off the joint from the pocket in which I had the cartilage isolated, I cut down upon it until the sac appeared. Stopping all hemorrhage, I then incised the sac, when the shining pearly button of cartilage presented, and was seized with mouse-tooth forceps and removed through the slit very much as one slips a button through a button-hole. The cartilage had no attachment, was a perfectly round flattened disk, three quarter inch in diameter, and upon one edge there was a short fringe by which it had originally been attached to the synovial membrane. No synovial fluid escaped, nor did air enter the joint, as I held my thumb down upon the bone, shutting the opened portion of capsule off from the rest. Catgut sutures were used for capsule and skin. No drainage was used, as I felt confident it would not be needed. An ordinary dry aseptic dressing was applied, the leg put on a posterior splint, and the patient was kept in bed for four or five days. There was no rise of temperature whatever nor any local disturbance. He very soon left off the splint, and resumed walking with perfect use of the leg. The knee was capable of the fullest flexion and as good as new. It is now eight months since the operation, and he has had no trouble with his knee at any time since the cartilage was removed.

In cases where the cartilage is so freely movable and hard to retain in sight, I believe the above operation is better than to open the joint in the usual manner under anæsthesia and fish for a loose cartilage which may require very considerable manipulation within the synovial sac before it can be grasped and removed.

CYST OF PHARYNGEAL TONSIL.

By ANNETTE E. LAMPHEAR, M.D.,
NEW YORK.

On February 2, 1894, G. M——, male, aged twenty-four, Swede, cook by occupation, came to Dr. Jonathan Wright's clinic at Roosevelt Dispensary for treatment of "catarrh."

The patient's family history was good. The personal history was somewhat vague. About ten months ago he had a sore throat, which was probably a peritonsillitis. Has had no aural trouble, no nasal obstruction, but for an indefinite time a great deal of post-nasal dropping, and expectorates very much mucus.

Examination of nasal fossæ and oropharynx showed nothing particularly abnormal, but on introducing a post-nasal mirror the vault of the pharynx seemed low. This appearance was seen to be due to the projection downward from the middle of the vault of a slightly oblong body about the size of a bean. The membrane covering this projection was smooth, and differed none in appearance from the remainder of the naso-pharynx. The diagnosis of cyst was made and verified by a digital examination.

After cocainization the mass was removed with post-nasal forceps, its detachment requiring considerable traction. The cyst cavity was filled with plugs of inspissated mucus.

The microscopical examination of its wall showed both the outer and inner surface to be covered with stratified pavement epithelium. The inner surface was smooth, excepting near its attachment to the pharynx, where there were a few crypts. The mucous membrane was rich in lymph corpuscles, but there were very few lymph follicles.

It would seem that this cyst resulted from adhesions between the lateral folds of a hypertrophied pharyngeal tonsil, its wall being formed by the complete closing in of the median fissure. The form of epithelium, stratified pavement, I think, is somewhat unusual, most authorities giving the ciliated columnar as the type of the naso-pharynx. This is the only case of retention cyst in over five thousand patients treated in the Throat Department of Roosevelt during the last six years, and I have been able to find only one other case reported in our American journals, that of Dr. Wright's, in the Philadelphia *Medical News*, of 1889.

Extract of Leeches in the Prevention of Thrombosis.—Dr. Sahli reported to the International Medical Congress that an infusion of leeches given by intravenous injection would prevent thrombosis. From experiments made on rabbits it was found that an infusion of the head of one leech to every two ounces of blood in the body was the required dose. For a man weighing one hundred and thirty pounds, between eighty and ninety leeches would be needed. As the effect of the remedy is not permanent, it being found necessary to repeat the injection at short intervals, it is improbable that this new medicine will find a very wide application.

Progress of Medical Science.

The Etiology and Treatment of Hydronephrosis.—The surgical treatment of various pathological conditions of the kidney has of late years come very prominently to the front, thanks in great part to the improvements that have been introduced into the *technique* of the operative procedures, improvements which have had for effect to make nephrectomy about as safe as an ordinary ovariotomy, and that is saying a good deal. The affections of the kidney in which the surgeon has shown himself able to intervene with a fair amount of success are hydronephrosis and pyonephrosis. Pyonephrosis comprises two varieties, which require to be distinguished both on pathological and on therapeutical grounds. There is one form associated with calculus. In this form it is *pyo*nephrosis from the commencement, and should be dealt with preferably by nephrotomy and drainage, especially if by the removal of the obstructing calculus the patency of the ureter can be restored. The other form occurs as the result of suppuration in a hydronephrosis. In this form the disorganization of the secreting portion of the organ is usually so complete that nothing remains but to remove the cyst which has become a source of danger to its possessor. In a paper which Mr. Bland Sutton recently read before the Medical Society of London, he pointed out that to cause hydronephrosis the obstruction to the flow of urine must be incomplete, or, if complete, intermittent, because sudden complete and permanent obstruction tends to cause atrophy rather than dilatation of the kidney. This tendency to intermission is one of the most remarkable phenomena associated with hydronephrosis, which thus simulates the "phantom tumors" dear to gynecologists. When bi lateral, the intermission may be alternate, and the diagnosis then presents less difficulty. The most curious feature about these cases of hydronephrosis is that though an obstruction to the flow of the urine must presumably at some time or another have existed, no trace of the original obstruction is sometimes discoverable during operation or *post mortem*. This fact is perhaps, after all, not so surprising as it looks at first sight. It is quite conceivable that the original condition which gave rise to the obstruction may have become obliterated by the grave changes, both in the kidney and in the neighboring structures, involved by the formation of an extensive hydronephrosis. Thus a movable kidney which originally rejoiced in sufficient mobility to kink or otherwise obstruct the ureter, may subsequently, when developed into a cyst of considerable dimensions, have contracted adhesions, thus disguising the primary cause of the obstruction. It is assumed, moreover, that obstruction of the ureter low down is invariably associated with dilatation of the ureter right up to, and including, the pelvis of the kidney. Mr. Henry Morris pointed out that this conception tended to mislead, because in some cases the ureter may bulge in a particular spot as the result of internal pressure acting on walls of unequal resistance, and that spot may be near the pelvis of the kidney, in which event the dilatation would probably be confounded with that of the kidney pelvis; or the bulge, if lower down, may compress the ureter above it as an aneurism sometimes does in respect of the artery on which it is situated. It follows that non-dilatation of the ureter throughout the whole or the greater part thereof does not preclude the possibility of the hydronephrosis being due to some obstruction low down. Hydronephrosis is a curiously silent affection; indeed, the only symptom for a long time may be an increase in micturition. This is particularly the case in respect of unilateral nephrosis, which may form without any indication of renal disease, and may remain unnoticed and undiagnosed until by its size it gives rise to symptoms incidental to the presence of such a growth. In the double affection the same silent course may be pursued, until the kidney substance has become so much degenerated that enough does not remain to provide for contingencies, and then the slightest strain on the excretory organs may determine grave symptoms of renal inadequacy. It is now generally conceded that in presence of a hydronephrosis, *a fortiori*, if suppurating, and provided the other organ is in good working order, the best course is to remove it by nephrectomy. Inasmuch as it is essential to ascertain for certain the condition of the other organ, the surgeon is advised to proceed by a median incision through the front of the abdomen, through which he can without difficulty examine the condition of both kidneys. Should he deem it expedient to remove the diseased organ, he then closes the anterior wound, and turning the patient over, removes the kidney through a lumbar incision—that is to say, without entering the peritoneal cavity. This is a point worth bearing in mind by gynecologists, who not infrequently stumble on a renal tumor which has been cut down upon under the impression that it was ovarian or uterine. In the flurry of the discovery the gynecologist is tempted to go ahead and to remove the organ through the peritoneum, instead of closing the original wound and attacking it from behind, thereby adding considerably and needlessly to the risk of the intervention. Altogether the question is a very interesting one, for it is full of promise in a department where formerly little or no hope could be entertained of affording relief.—*Medical Press.*

Sloughing of Cervix after Labor; Recovery.—Dr. Magnaux has observed this complication in a woman, aged thirty-eight, who had been twenty times pregnant—twelve labors at term, one in the middle of the sixth month, and six miscarriages, while the twentieth pregnancy began at the end of November, 1892. She was seen at the Hôpital Tenon in April, when no morbid history could be traced. On August 26, 1893, labor set in at 10 P.M. She was delivered at 9 A.M. the next morning, having been admitted into the same hospital. The cervix, it was noticed, was never entirely effaced, and during the efforts at expulsion the anterior lip projected at the vulva, and appeared œdematous and deep violet in color. The child was very big, and there was some trouble in delivering the shoulders; the head had presented in the first position. The left arm was damaged, but the child was saved. The cervix uteri of the mother was found next day lacerated on both sides. A part of the posterior lip was found partly detached. The anterior lip, over three inches long, projected at the vulva; it was sloughy. The vagina was syringed daily with lysol, and the cervix painted with iodine and iodoform gauze passed into the cervical and vaginal canals. Within a week the sloughy tissues had separated. By September 12th, no trace of any anterior lip remained, the posterior lip was very thin, and about half an inch long. The child's left arm remains partially paralyzed.—*Archives de Tocologie.*

The Antiseptic Power of Ichthyol.—As the result of recent experimental studies Dr. Abel states that: 1. The ichthyol preparations in weak solutions, and in a short time, destroy the pyogenic and erysipelas streptococci. The action of various commercial preparations is practically identical. Ichthyol is used with success in the suppuration from these cocci. 2. The staphylococcus aureus and albus, the bacillus pyocyaneus, the bacillus of typhoid, ozæna, and anthrax, the spirillum of Asiatic cholera, show more or less resistance to ichthyol, in that when pure it must act upon them by the hour in order to destroy these organisms in cultures. 3. The diphtheria bacillus in fresh colonies is easily destroyed by weak ichthyol solutions, while mature ones are acted upon with difficulty. Therefore it is useful in diphtheria only in prophylaxis. 4. Ichthyol has rendered good service in the treatment of typhus and ozæna, although it can only with difficulty make harmless these infections. 5. It is recommended that it should be preserved only in substance or in a fifty per cent. solution; weaker solutions may be culture mediums for micro-organisms. Weak solutions should be sterilized by heat, which has no influence upon its properties.—*Centralblatt für Bakteriologie.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS
WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, August 4, 1894.

THE VALUE OF LIFE IN CASES OF ACCIDENT.

THE recent action of the Committee on Preamble of the Constitutional Convention of the State of New York, in favor of retaining the limit of damages by railroad accident resulting in loss of life to five thousand dollars, has naturally given rise to some adverse criticism by the daily press. The objection taken is founded upon the absurdity of allowing any limit for damages short of killing, and stopping by legal enactment at the sum of five thousand when the victim is entirely sacrificed. The question resolves itself into the ridiculous solution that a part is of more value than the whole. In other words, it appears to be cheaper to kill a man outright than to strain his back, put out an eye, crush his foot, or maim his hand. In the former case he is done for at once, his earning capacity is at an end, and the railroad companies give the price for the carcass; while in the other the probabilities of his still being able to earn something of a living are offset against any sum of damages within the range of the sympathies of the jury.

The real question bears upon the earning capacity of the victim. It is well known that a wide latitude, in case of maiming, is given in determining the relative earning capacity of different individuals, and damages are awarded accordingly. Why the relative value of lives should not in such a score be equally considered does not appear. The life insurance companies, in questions of life expectation at given ages, with different surroundings and with stated hereditary proclivities, have reduced the charges to mathematical calculations and govern their premiums accordingly. But by the present rule all lives are equal before the law, no matter how young or old the victim may be, what his earning capacity has been proved to be, what his future might reasonably guarantee, and what the degree of loss may be to his dependent family. In this respect the ordinary day laborer, with an earning capacity of two or three dollars daily, is on an equal footing with the professional man, the expert artisan, or the progressive tradesman whose possibilities are almost without limit.

If we rest the claim for damages upon the basis of reasonable expectation of earnings, which, in fact, is the only way of proper adjustment, we are forced to admit that the highest award should be rendered in case of death; while in mere maiming the parties accountable for the same should pay in proportion to the degree and extent of the incapacity occasioned by the particular injury. If the jury is competent to decide the extent of damages in one case, why not in the other? To the medical man, who is accustomed to weigh all the circumstances in the cases of injury, this is the only way to do justice to all.

The railroad companies are, of course, in favor of the statute as it now is, the reasons for which are too obvious for mention.

LAWYERS ON THE FEES OF DOCTORS.

FOR some reason, lawyers have developed a special tendency to lessen the monetary value of physicians' services. It is the common experience that a doctor's bill which has to be *visèd* by a lawyer will surely be cut down. Laboring men, business men, corporations, and most classes of society, even including clergymen, are usually willing to pay for medical services; but the lawyer seems always to think them appraised too high. This at least is the complaint which is often made to us. And quite in harmony with this is an editorial expression on the subject by the New York *Law Journal*. The editor says:

"In dealing with rich patients and clients, physicians and surgeons, and lawyers acting in cases not involving specific property, should make out their bills not commensurately with the wealth of their employer, but simply on the basis that he is rich enough to pay whatever is right. The charges should be fixed according to the practitioner's standing and experience and the amount of labor involved, the customary rates of practitioners of equal standing in the same community for similar services being kept in view as a guide and a possible corrective. This general rule would not preclude the acceptance of smaller fees from poor people, but it would debar a practitioner from charging a man worth $1,000,000 more than one worth $100,000 for the same service. We believe it is essentially communistic and subversive of professional conscience and dignity to charge a rich man all that can be screwed out of him, in order to make up for what one thinks he ought to have received on account of professional acts of charity or mercy."

The wording of the above is ingenious, and the plea made has an air of justice. Certainly no one will disagree with the statement that "a rich man should not be charged all that can be screwed out of him." But it would be inferred that no less should be charged for a capital operation on a person of very moderate means than for one done on a multiple millionaire, or a person upon whose life depends the safe and productive management of some great industrial, social, or political work. The fact is, we believe, that most surgeons have a certain scale of maximum and minimum fees. The maximum is a fixed one and is applied to the wealthy. All would apply it to millionaires, while few would apply it to a person worth one-tenth that sum, since this does not by any means make him wealthy if he lives in this town.

Bellevue Hospital.—Plans are being made for the reconstruction of certain portions of Bellevue Hospital, New York, that part which is used as reception office, examination and admission rooms, besides store-room of the hospital.

DOCTORS AND DEFINITIONS.

A CERTAIN weekly paper in this town has adopted the practice of publishing some scurrility about the medical profession in each issue. This is not a matter of very much importance; still it possesses some academic interest to physicians, who, as a rule, take both eulogy and satire in a very equable manner.

What one might object to as regards this particular departure in journalism is the fact that the man who does the medical items in the aforesaid weekly gets them out of ancient jest books, which is, we think, a wrong practice and dishonest to his readers. For example, the latest medical joke is a "Definition of a Doctor," this definition being: "A person who, when you are ill, comes and guesses what is the matter with you." Now, this is very good and amusing, but it is not as good as the definition given by Voltaire (A.D. 1740), to the effect that "a doctor is a person who pours drugs of which he knows little into a body of which he knows less." Yet it is evidently the same idea. Swift's satire was equally brilliant. "Apollo was the god of physic and the sender of diseases. Both were originally of the same trade and continue so." And something in the same line was the epigram of Martial:

> "Diaulus, the doctor, was a sexton made,
> Though he is changed, he changeth not his trade."

The material for similar definitions of doctors exists in literature from ancient to modern times. It is resurrected at regular intervals and is always the same. The point is, that doctors are ignorant, useless, avaricious, pretentious, dishonest, slayers of men, or else that they are promoters of suffering, heartless, and brutal vivisectors. The jokes always show that doctors do not know, they only guess; they do not cure, they only pretend; they do not tell the truth; they carve up living animals who all the time suffer conscious and excruciating agony; they enjoy the misery of others, and they work to prolong it; their bills are high, their labor light, their responsibilities trivial, and their rewards in money and appreciation enormous.

This is the sum and substance of the medical jokes of the past two thousand years. They are all in print, or at least samples of them, and form a part of accessible literature. We could refer the amiable malefactor who writes his weekly medical jokes in this New York paper to the volumes in which all the above facetiæ are compiled, but he shows that he possesses it.

Why not, however, give the world some new jest on the evils of medicine, or else give proper credit to our sympathetic critics of the past?

And why not sometimes be pleasant also and show the other side? Even Voltaire, who was a bigger man after all than the average New York jest-maker, said:

"Nothing is more estimable than a physician who, having studied nature from his youth, knows the properties of the human body, the diseases which assail it, the remedies which will benefit it, exercises his art with caution, and pays equal attention to the rich and the poor."

Mr. Lawson Tait was going to move to London, according to some of the English papers, a year or so ago. Now the American papers state that he is going to Chicago.

News of the Week.

Rewards for Fecundity.—The Province of Quebec has a law bestowing 100 acres of government land upon every father of a family who has twelve living children, issue of a lawful marriage. Up to the present 174,200 acres of rich agricultural land have been given away in bounties to 1,742 fathers of twelve or more children, who have complied with the conditions of the act. Not all of these proud fathers, however, are satisfied with the amount of the bounty, for instances of families of twenty or more children are not rare, and the fathers of these want a proportionately higher reward for their patriotic efforts. One old gentleman, Mr. Paul Belanger, of River du Loup, wants 300 hundred acres, and bases his claim upon the fact that he has thirty-six living children. Another claimant for an increased allowance is Mr. Theoret, of St. Genevieve. His wife, who is but thirty years of age, has presented him with seventeen children. She has just given birth to triplets for the second time in five years, and has had twins three times. Mr. Theoret hopes to acquire a large portion of the Province if his wife will continue to do her share.

Medical Education in China.—Western medicine is slowly making its way in the Celestial Empire, under the fostering care of the progressive Viceroy Li Hung Chang. The medical school established by him in Tien Tsing is in a flourishing condition, and it has been decreed that the medical officers of the army and navy shall in future be taken from its graduates. The medical stores for use in both services must first be approved by the faculty of this school.

Professor Max von Pettenkofer has resigned from the University of Munich. The cable reports that this has aroused a great deal of public indignation, as it is understood that the resignation was enforced by pressure from Berlin in consequence of Dr. Pettenkofer objecting to some of the anti-cholera measures recommended by Professor Koch.

The American Association of Obstetricians and Gynecologists will hold its seventh annual meeting at Toronto, Ont., Wednesday, Thursday, and Friday, September, 19, 20, and 21, 1894, to which a cordial invitation is extended to the medical profession.

The German Association of Scientists and Physicians will hold its sixty-sixth annual meeting in Vienna during the week ending September 30th. The Austrian Government has made an appropriation of $5,000 to defray the expenses of the meeting.

A Russian Leper Colony. The St. Petersburg correspondent of the London *Daily Chronicle* states that the general governor of the Amoor province is arranging in the vicinity of Nicolaivsk for a colony of lepers, which will be surrounded by a stockade, to prevent the patients leaving the place. Land is being set apart within the enclosure for gardens and the necessary buildings.

The Kentucky School of Medicine.—At the meeting of the Association of American Medical Colleges, held in San Francisco on June 7, 1894, the Kentucky School of Medicine, of Louisville, Ky., was dropped from membership in the Association.

The University of Halle has been celebrating the second centenary of its foundation on Thursday, Friday, and Saturday of this week.

Dr. Jules Comby, of Paris, editor of the *Revue Mensuelle des Maladies de l'Enfance*, has been created Chevalier of the Order of the Crown of Italy.

Dr. Paul Berger has been appointed to the chair of Clinical Surgery in Paris, vacant through the death of Dr. Léon Lefort.

The Mortality in Rio de Janeiro, for the second half of the month of March, was at the rate of 65.31 per 1,000 inhabitants.

The Plague Bacillus.—Dr. Kitasato, the Japanese bacteriologist, has been investigating the plague in Hong Kong, and believes he has found the cause of the disease in a bacillus resembling somewhat that of anthrax. It consists of short, slender, straight rods. Animals inoculated with cultures of this micro organism died with symptoms of the plague.

Tractions on the Tongue for Asphyxia.—M. Laborde has recently published a small work on this method of treating the apparently dead, in which he describes the procedure as follows: Seize the anterior third of the body of the tongue firmly between the thumb and index-finger, using a towel or handkerchief to prevent slipping. Then make strong, repeated, rhythmical tractions on the organ, from fifteen to twenty times a minute, imitating the rhythmical respiratory movements. The operator must be sure that the root of the tongue is drawn up with each movement of traction, a very easy thing to do when asphyxia is profound. The first sign of returning consciousness is a resistance to this drawing up of the root of the tongue. One or two movements of deglutition are then usually made, followed soon by a noisy inspiration, which Laborde calls the "inspiratory hiccup." The operator is cautioned to persevere in this procedure in spite of apparent insuccess, the author having seen the first indications of returning life appear after tractions had been practised for over an hour. M. Laborde's explanation of the mode of action of this procedure is that two extremely sensitive nerves supply the tongue, namely, the glosso-pharyngeal and the lingual, while the superior laryngeal sends several filaments to it. These nerves, taking their origin directly or indirectly fron the respiratory centre, stimulate it when stretched, and the bulb stimulates, in its turn, the phrenic nerve which supplies the diaphragm.

A Medical Press Association is to be established in Germany after the model of a similar organization already existent in France.

Professor Czerny, of Heidelberg, who recently declined the chair of surgefy in Vienna, is said to have been led to take this step through a misunderstanding of the conditions. The call has now been accepted by Gussenbauer, of Prague. Dr. Mikulicz, of Breslau, was the third candidate nominated by the professorial college to fill Billroth's place.

Kumyss Poisoning.—A number of persons in one of the health resorts of the Caucasus were poisoned last summer by ptomaïnes in the kumyss which they drank. An investigation showed that the maker had neglected to scald out his barrels, and he was thereupon sentenced to six weeks' imprisonment and to pay the costs of the investigation.

A Lapsus Calami.—In the issue of June 30th, we noted a fortuitous combination of items, in which the notice of a meeting of a medical society was immediately followed by a prescription for sexual debility, and erroneously attributed the same to the *Journal of the American Medical Association*. Our esteemed contemporary very properly confines advertisements of proprietary medicines to the outside pages where they belong, and we regret having, through pure accident, done it this injustice.

The Hospital for Consumption at Ventnor has received a gift of $10,000 from an anonymous donor in memory of two daughters who died from phthisis.

Professor Madelung, of Rostock, has been appointed Professor of Surgery in the University of Strasburg in succession to the late Professor Luecke.

Anomalous Fœtal Nutrition in Twin Gestation.—In the article with this title by Dr. John C. Hupp, published in the issue of July 21st, the words, "the cord of the smaller fœtus," were omitted in the ninth line. It should have read: "There was only one placenta, which was attached to the ordinary sized cord of the larger fœtus. The cord of the smaller fœtus, which was not larger than a thread, encircled its neck," etc.

Professor Joseph Hyrtl, who died recently in his home near Vienna, at the age of eighty-four, was best known, perhaps, as an anatomist, but he was besides a remarkable linguist, an original investigator, and an eloquent lecturer. He was one, and the last survivor, of the brilliant coterie of scientists who made the Medical School of Vienna so celebrated throughout the world. A writer in the London *Telegraph* says that, "as a teacher, Professor Hyrtl was almost unsurpassed. He was so gifted with eloquence that his lecture-room could only with difficulty accommodate the crowds of students of all nationalities that flocked to hear him. As an original investigator and scientist, Professor Hyrtl attracted the warm admiration of his contemporaries. He was the first German writer who published an independent treatise on topographical anatomy. His celebrated handbook on that subject appeared in 1847. With the publication of his 'Lehrbuch der Anatomie des Menschen,' of which the twentieth edition has appeared this year, a new era was opened in anatomical text-books. His books have been translated into all European tongues. Professor Hyrtl's celebrity as a linguist is well known. He had so completely mastered the tongue of Cicero that it became in his mouth a living language, and he was always prepared to give the fullest explanations in elegant Latin to all inquirers. His knowledge of the Greek classics also was amazing, and in 1861 he delivered before the Paris Academy a much-admired extemporaneous lecture in the French language. In his seventieth year he took up the study of Hebrew and Arabic with such success that three years later he was able to produce his remarkable work upon the anatomical ideas of the Jewish and Moorish physicians. Hyrtl was distinguished for his benevolence, and, considering the modest amount of his income, his benefactions were as-

tonishing. He supported poor students and benevolent institutions in a generous fashion. He caused two orphan institutions to be erected in Mödling, near Vienna, to accommodate two hundred orphans, and thus bestowed on Lower Austria a gift that cost him £30,000."

The Cholera.—In St. Petersburg the epidemic appears to be abating somewhat, the number of new cases daily reported being reduced to about eighty, and of deaths to between forty and fifty. The disease is spreading, however, in Austrian Galicia near the Russian frontier, and prevails to an alarming extent in the district of Cracow. In Marseilles also many cases of cholera have been reported during the past week, and the Spanish consul in that city has informed his government that the epidemic is spreading with great rapidity, although the local authorities deny its presence. The disease is present in many towns in Belgium along the river Meuse, and thirteen cases with six deaths are reported in Maastricht, Holland, situated lower down on the same river—another fact, if any more were needed, in support of the theory of the water-borne nature of cholera, so strenuously insisted upon, among others, by Ernest Hart. In Radom, in Russian Poland, a serious riot was occasioned by the attempt of the authorities to bury the bodies of a number of persons, who had died of cholera, in the cemetery of the town. A mob resisted this attempt and compelled the bodies to be taken elsewhere. They then made an attack upon the hospital and carried a number of sick persons out into the surrounding grounds. The police had hitherto been powerless, but they were reinforced by a detachment of gendarmes, who fired into the crowd, wounding many persons.

Dr. Francois Clément Maillot died in Paris on Sunday, July 29th, at the age of ninety years. He was made a member of the Legion of Honor in 1839, and held many high offices in the civil and military services between 1825 and 1860, and was a retired medical inspector of the French army at the time of his death.

Deaths from Sunstroke.—Statistics of the Health Department show that the number of deaths from sunstroke in this city in the past four years was: The deaths in 1890 were 62; in 1891, 95; in 1893, 43, and until July 26th of the present year, 40. In 1892, when there were 320 deaths, 29 occurred in June, 252 in July, and 39 in August. In each year two-thirds of the deaths occurred among males.

The Cancer Germ.—Dr. van Nissen, of Wiesbaden, has found a micro organism in cancerous tissue, which he is led to regard as the cause of the disease. In cultures the cell-groups bore a very close resemblance to the so called epithelial cell nests of carcinoma. He calls this new micro-organism claspodium cancerogenes, or, for the sake of brevity, canceromyces. The organism is described briefly in the *Centralblatt für die medicinischen Wissenschaften*, No. 21, 1894, but the author promises to present a more complete account of his experiments shortly.

Professor Nothnagel has become unpopular with the Vienna students by reason of his attempts to combat the anti Semitic agitation. The students recently made such an uproarious demonstration that the rector has ordered all the courses in medicine to be suspended.

La Revista de Tisiologia is the title of a new quarterly journal devoted to the study of tuberculosis. The editor is Dr. Valenzuela, of Madrid.

Chloroform Mortality in Melbourne.—An Australian paper points out that the mortality from the administration of chloroform in Melbourne is about three per annum in a population of 450,000.

The Use of the Decimal System of Weights and Measures is to be obligatory on physicians and pharmacists in Russia after the end of the present year.

Women are now allowed, through a recent decree of the sultan, to practise medicine in the Turkish dominions.

The King of Italy has given a prize of $4,000 to Drs. Tizzoni and Luciani for their experimental work on the functions of the cerebellum. And still the functions are somewhat in doubt, though these gentlemen have advanced our knowledge greatly.

Sewing-up Wounds by an electrical machine is one of the latest advances in surgical technique.

Physicians as Dispensers of their own Medicines.—According to a bill now before the French Senate, after passing the Chamber of Deputies, physicians are not to be allowed to dispense any medicine at all.

The New York Lying-in Asylum.—The managers of the New York Lying-in Asylum, which has for many years maintained an admirable out-door as well as in-door maternity service for the benefit of the poor, have secured, as the future home of their institution, the fine old mansion of the late Hamilton Fish, standing at the corner of Second Avenue and Seventeenth Street, and fronting on Stuyvesant Square.

Rochester (N. Y.) Hospital.—The Board of Managers of the Rochester State Hospital held its quarterly meeting July 17th, at which meeting the plans and specifications for a new building and repairs made necessary by the recent fire were forwarded to Albany for approval. The appropriation for the new building is $65,000.

A Protestant Hospital.—Articles have been filed for the establishment of a new hospital in the city of Seattle, Wash. The objects are to found and maintain a hospital under the management of Protestants, for the medical and surgical treatment of sick and infirm persons, with the object of furnishing such treatment, as far as possible, gratuitously to the poor.

The Memphis Board of Health has sent a communication to the Tennessee State Board of Health, calling for such action as will lead to legislation prohibiting infant and child life insurance within the State, on the ground that the practice leads to criminal negligence of the proper care of children, and is to that extent prejudicial to public health.

A New Fluke has been discovered in America by Professor Ward, of Nebraska. It is called the *Distoma Ringeri*.

Venereal Diseases in the British Army.—According to some statistics presented to the House of Commons by the war secretary, out of a total of 196,534 men in the British army there were in one year 52,155 admitted to hospitals to be treated for venereal diseases, or more than one-quarter of the effective force.

Congress of American Physicians and Surgeons.

Third Triennial Meeting, held in Washington, D. C., May 29, 30, 31, and June 1, 1894.

AMERICAN ORTHOPEDIC ASSOCIATION.

Eighth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from Vol. 45, page 766.)

First Day, Tuesday, May 29th.

The Etiology of Deformities in Knee-joint Disease.—Dr. A. E. Hoadley read a paper with the above title, in which he claimed, after experimenting with eighty different subjects, that the flexor muscles are under all conditions, except when paralyzed, stronger than the extensors. Also, that the flexor muscles may at certain times become extensors, and that in all ordinary deformities of the knee it is not the result of the flexors dominating over the extensor. The cause of flexion in case of disease was rather due to the pain, and consequent attempt, on the part of the patient, to change the position of the joint.

Dr. Wirt made a demonstration of the mathematics involved in the mechanics of the knee-joint.

Dr. Whitman asked if the gastrocnemius did not play an important part in the deformities at the knee.

Dr. Phelps said that the experiments of Dr. Hoadley differed from those of Haughton, of Dublin, who had done a great deal to make the subject plain; also from his own, which were published in the Transactions of the Association last year. He said that the extensor muscles lose force as flexion takes place, while the flexors increase in force as the limit of flexion is reached. Rotation is produced by the biceps muscle, which is absorbed into the head of the fibula.

Dr. Ridlon said as muscles reach their limit they lose strength.

Dr. Hoadley, in closing, said that Dr. Phelps's experiments had been limited to one case, while his own series rightly should have more weight. In reply to Dr. Whitman, he agreed that the gastrocnemius muscle was a powerful flexor.

Hoffa's Operation for Congenital Dislocation of the Hip-joint.—Dr. E. H. Bradford, of Boston, presented a pathological specimen from a child on whom he had operated for a congenital dislocation, the patient dying subsequently from diphtheria. The acetabulum in this case, while somewhat misplaced, was well formed. Owing to the abnormal position, he failed to find the acetabulum at the time of the operation, but had made a socket for the head of the femur at another place in the ileum. The speaker said that the specimen illustrated that there was danger from curetting too freely into the acetabulum of the cases, as the bone might be perforated. He also stated that Hoffa was wrong in the assertion that the acetabulum was the thickest part of the pelvis. A specimen of rachitic deformity of the hip joint was presented by the same speaker. The condition was similar to that described by Dr. Whitman.

Dr. Whitman emphasized the point that patients afflicted with congenital dislocation of the hip not only suffered great disability, but oftentimes had pain.

Dr. Ryan said he had not met with cases complaining of pain.

Dr. Weigel agreed as to the disability, and thought the specimen presented by Dr. Bradford showed that more might be obtained by treatment by traction.

Dr. DeForrest Willard thought that if all cases of congenital dislocation were like the specimen presented, the operation would be called for, as the acetabulum was deformed, and he believed it would be found even more so in the majority of the cases.

Dr. Bartow spoke of a case of congenital dislocation he had treated by traction, and the head of the bone remained in the acetabulum.

Dr. Wirt had seen cases who complained of pain when walking.

Dr. Phelps said dislocation might take place in any direction. He considered the operation justifiable, as not a single case had been cured otherwise. Hoffa had said to him that he did not operate after the patient was four years of age.

Dr. Bradford, in closing, confirmed what had been said about pain and disability. He considered it important to obtain union by first intention in Hoffa's operation. Dr. Phelps's remarks he considered theoretically correct, but he had seen adults without much disability.

Second Day, Wednesday, May 30th.

Flat-foot.—Dr. Royal Whitman, of New York, opened the discussion on this subject. He did not believe that flat-foot is caused by shortening of the tendo Achilles, but rather that it is due to a disproportion of the weight thrown on the arch of the foot when in a faulty position. Flat-foot he considered a dislocation of the bones of the arch, which must be reduced and kept so by some form of apparatus which will not restrict the tendinous or muscular structures which assist in maintaining the arch. It is usually advisable to forcibly correct the deformities under ether, even over-correcting the deformity so as to produce a club-foot, and apply a plaster-of-Paris splint so as to temporarily hold the foot in this position. He does not advocate the cutting operation, but considers the prognosis good when his line of treatment is followed out.

Dr. Shaffer, of New York, in calling attention to the mechanism said that studies must be made from the normal foot. Flat-foot, he believed, was due to shortening of the gastrocnemius muscle, while paralysis of the same muscle resulted in talipes calcaneus. The reason he gave for not having flat-foot in cases of talipes equinus was that the relation of the axis of the leg to the mediotarsal joint was changed. In no case of flat-foot was the gastrocnemius ever elongated.

Dr. Wirt thought that Dr. Shaffer was in error as to the mechanical principles involved. By his model he has shown a difference in the force exerted on the astragalo scaphoid joint and the breaking down of the arch when the tendo Achilles is shortened by representing that the heel rises in this condition, while in the normal foot he represents flexion of the tibia forward at the ankle joint without any rise of the heel. Now, in truth, do we walk in this manner? In the act of walking the muscles of the calf are contracted. The tendo Achilles is pulled upon and the heel rises from the ground, the weight being borne upon the ball during fully one-half of the step. The difference in length between the normal tendo Achilles and one slightly shortened would be made up by a greater and earlier contraction than in the case of the normal, which would put the foot upon the ball in about the same length of time.

Dr. McCurdy said that Marks had shown that motion at the ankle joint was not necessary for comfort in walking.

Dr. Ketch asked Dr. Shaffer if it was first necessary that we should have equinus before flat-foot occurred.

Dr. Bartow thought the gastrocnemius muscle is shortened in flat-foot, but that this usually takes place after the change in the arch of the foot.

Dr. Weigel suggested the taking of a series of instantaneous photographs of a man in the act of walking, so as to test the position of the ankle joint.

Dr. Shaffer, in closing, said it was necessary that the motion of the ankle-joint be stopped at a certain point which throws the weight upon the medio tarsal joint and thus produces flat-foot. He had employed an instrument for stretching the gastrocnemius muscle in cases of flat-foot.

Rachitis.—Dr. A. Jacobi, of New York, in opening the discussion, said that rachitic deformities represented

a comparatively new disease in this country. He remembered when it was difficult to find a sufficient number of cases for his clinics. Some of the appearances and general physiognomy of rachitic children are as follows: Less hair on the head; the veins are more dilated; the head has a quadrangular appearance and may be hydrocephalic; the forehead is more prominent, the bones in this region may be two or three times the normal thickness, this may all disappear, but often some deformity remains; the teeth are irregular and decay early; the second crop are usually hard and of a yellow appearance; we may have the Hutchinson teeth in rachitic children; the trunk is short in these cases, clavicle is thickened; chest prominent anteriorly, lower ribs stand out, and the rosary may appear as early as the second month. May have kyphosis or scoliosis of the spine; pelvis is rarely deformed, but adults who have been the subjects of rachitis may have undeveloped pelves; the sacrum is usually more steep in the rachitic child; the extremities suffer greatly in this condition; the epiphyses are painful, the diaphyses are usually bent; fractures are rare because of the periosteal thickening; the ligaments are flabby and soft; the periosteum suffers from rachitic deposits; there may be hemorrhages during the course of this disease which are not due to scurvy; deformities are due to changes in the epiphyses, and when calcification takes place growth stops. The general system and the muscles, both the voluntary and involuntary, suffer as much as the bones; this is not paralysis but simply a weakness; the heart is large and the arteries are small, the cause and effect of which it is difficult to decide; the stomach is dilated; constipation is usually one of the first symptoms. Other internal organs may be displaced.

Dr. Benjamin Lee, of Philadelphia, said that rachitis in its earlier stages was most marked in the structures where the lime salts and phosphorus should be most prominent. The child may appropriate the fats and yet fail to assimilate the salts. Constipation is usually present, or the patient may have diarrhœa. It sleeps poorly, and this restlessness may be the only symptom for the first few months. Convulsions are not uncommon, twitching of the muscles of the eyes, spasm of the muscles of the larynx, and vaso motor disturbances are common; bronchitis is very frequent. Nerve starvation, he says, explains many of these phenomena. The deformities the result of rachitis are numerous.

Diagnosis.—Acute rheumatism, he said, was rare in young children; the absence of snuffles and sore throat ruled out syphilis. In considering the prognosis, the author thought that death was often due to rachitis which had not been diagnosed. The most important point in the treatment was diet. Exercise, both passive and active, he said, would often prevent deformities. One question which he brought out, regarding the sterilization of milk which had become so prevalent during the past few years, was to the effect that the lactic-acid ferment, which is destroyed by this process, might be necessary to take up the salts. This he thought was the reason why the wealthy as well as the poor suffered from this disease.

Dr. Samuel Ketch, of New York, said that the orthopedist did not have the opportunity of seeing cases of rachitis in their incipiency. He does not think sufficient attention is paid to prophylactic measures. Many of the deformities are due to faulty positions assumed while rachitis is present, and he suggested the use of portable frames so as to enable these cases to get fresh air. Braces, he thought, should not be used on the very young, but massage and manual force would usually suffice to overcome these deformities. All apparatus applied to cases of bow-leg and knock-knee should be frequently observed by the surgeon, so that its shape might be changed to meet the exigencies of the case. Massage should be done in all these cases, even though they be under mechanical treatment. Frequent tracings of the deformities should be made. Operation should not be resorted to in rachitic deformities until eburnation of the bones has taken place.

Third Day, Thursday, May 31st.

Correction of Rachitic Deformities.—Dr. DeForrest Willard, of Philadelphia, said that the deformities might be corrected by apparatus before solidification of the bones had taken place, but it was often difficult to have the treatment properly carried out at home, and he was of the opinion that the correction of the deformity by a greenstick fracture, produced by manual force, was preferable. When it was necessary to use the osteoclast, he said the epiphyseal line should be avoided. Osteotomy he considered frequently necessary in extreme cases, especially in large children and adults. The anterior curves of the tibia, he said, were extremely difficult to correct by apparatus, and for this, osteoclasis by manual force, or osteotomy, should be performed. He had abandoned the cuneiform osteotomy, as a simple division of the bone had proven quite as satisfactory. The author thought that osteotomy was indicated nine times out of ten. Osteoclasis, he said, pulpifies the soft parts overlying the bone. In performing an osteotomy he does not use the Esmarch bandage, as the hemorrhage which takes place prevents infection from without.

Dr. Weigel asked Dr. Willard if he now advised the use of drainage, after operating upon the anterior tibial curvatures, as he once did. Dr. Weigel had not found the drain necessary. He thought more of osteotomy than of osteoclasis.

Dr. Ryan, also, agreed that osteotomy was more exact than osteoclasis. He said that cuneiform osteotomy was practically abandoned, except for anterior tibial curvatures. He asked Dr. Weigel if he sewed up the wounds. Dr. Ryan did not think any case should be operated upon, before four and a half years of age, as the deformity was likely to relapse. Deformities often improve without any treatment, as was shown by a family of children, residing near his office, who had received no medical attention whatever.

Dr. Gillett had never performed osteoclasis. He preferred osteotomy. He spoke of an accident following osteotomy, in which he failed to get perfect correction of the deformity, the patient became dissatisfied, and he was unable to follow up the case.

Dr. Cook, while he preferred osteotomy to osteoclasis, said the results were not always good.

Dr. Bartow did not think the fear of injuring the soft parts was well grounded. In exceptional cases, where the bone was hard, osteotomy should be performed. He thought it possible to correct some of these deformities, without even breaking the bone, by means of the osteoclast.

Dr. Townsend said that one of the advantages claimed for osteoclasis was that the bone was broken without being converted into a compound fracture.

When Mr. Grattan visited America, he had seen him use his osteoclast on two different cases, and in both considerable laceration of the soft parts was produced. While neither of these patients had any trouble following the laceration of the soft parts, he thought there was considerable danger of getting such a wound infected from the instrument, which was not aseptic, or from the patient himself, because the limb is rarely prepared for this operation, as it would be for osteotomy.

Dr. Coolridge said he thought a great deal depended upon the instrument employed. With the Lorenz osteoclast he had never seen the skin broken.

Dr. Bartow said that he always protected the skin, over the region to be operated upon, with moleskin plaster.

Dr. Ketch did not agree with Dr. Ryan, that cases got well without treatment. He believed, in all instances, massage had been employed at home.

Dr. Lee thought that with osteoclasis a simple condensation, without displacement of the soft parts, would result.

Dr. Willard, in closing, said he rarely performed the cuneiform osteotomy at present, as he had gotten excel-

lent results from the simple linear division of the bone, which was just as strong afterward, and the recovery was much quicker. When he does perform cuneiform osteotomy now, the wound is left open without drainage, as he does not think much of union by blood-clot. On the contrary, he thought large blood-clots sometimes prevented the callus from being thrown out. After all osteotomies he emphasized the importance of over-correcting the deformity. The details of after-treatment, of applying the plaster of Paris, should be done by the surgeon, and not by his assistant.

Rubber Heels for Patients with Pott's Disease.—Dr. John Schapps, of Brooklyn, N. Y., presented a shoe with the rubber heels attached, which he said was employed for the purpose of overcoming concussion of the spine while walking. This simple procedure had given considerable relief to the patients.

Elastic Traction in the Immediate Treatment of Club-foot.—Dr. Bernard Bartow, of Buffalo, read a paper with the above title, in which he advised division of the contracted tendons and the correction of the deformity in club-foot as early as at three weeks of age. When once the foot is gotten into the normal position, he advises the use of elastic traction, because the foot is not restricted, as when immobilized with plaster of Paris and other braces, and thus atrophy of the muscles does not occur. The elastic traction is made by rubber bands, extending (1) from the knee to the foot, for overcoming the equinus, and (2) others on the outside of the foot, for overcoming a varus. These rubber bands are fastened to attachments, which are held in position by adhesive plaster. When the two sets of bands are applied, one, for the purpose of abducting and rotating the foot outward, the other, for overcoming the equinus, the force to be exerted can be regulated by the number of bands. It was advisable to instruct the mother, after the adjustment of the above-described apparatus, to manipulate the foot at regular intervals, so as to over correct the deformity, by which means the atrophy of the muscles, which would occur if an immobilization apparatus were applied, is prevented.

Dr. Shaffer was of the opinion that continuous and intermittent traction had their places. As to nutrition, he had seen muscles develop very perceptibly in a few weeks after intermittent, forcible traction.

Phelps's Method for the Cure of Club-foot in Adults.—Dr. William E. Wirt, of Cleveland, in concluding his remarks on the above subject, said that adults and older children would not endure the amount of traction necessary to correct these extreme deformities, and that even tenotomies, combined with tarso-clasis, were not sufficient to cure the cases, although the deformity might be temporarily corrected. Not infrequently it is necessary to divide the plantar structures openly, after the method of Phelps, and divide the tendo Achilles, together with the application of tarso clasis, to be able to overcome the deformity. In the worst cases, in addition to the above, it will sometimes be necessary to remove the wedge-shaped piece of bone from the tarsus.

Discussion.—Dr. Weigel said the term "cure" should not be applied to these cases of club foot, as he considered only improvement was obtained. He reported a case of double congenital club-foot, and double club-hand, and presented a photograph of the same before operation. On the right foot he had performed Phelps's operation, and later, cuneiform section of the bones of the leg, just above the joint. The operation performed upon the left foot consisted in the removal of the head of the astragalus. The Phelps operation, he says, does not answer in the extreme cases, but must be supplemented by the removal of bone. He does not agree with Dr. Wirt in his idea of dividing the tendo Achilles by an open incision, but thinks the subcutaneous method just as good.

Dr. Townsend said that with all due deference to the Phelps operation, it was not always successful; and he believed the force applied by the long lever, after the incision had been made, was very essential. The Phelps operation, he considered, had a limited field.

Dr. Ketch said that Dr. Weigel's case suggested a spastic condition, nor did he think the Phelps operation had a broad field.

Dr. Houston, of Montreal, said he did not think the surgeon should be wedded to any operation. The individual case, he said, should always be considered.

Dr. Coolridge spoke for Dr. Myers, who had to return home, and described an operation for club foot, in which he made a small incision over the most prominent bony deformity; through this he inserted a scoop for the purpose of removing the bone. Then the foot is forced into position.

Tarso-clasis.—Mr. Nicholas Grattan, F.R.C.S., of Cork, Ireland, in a paper on the above subject, said he had, during the past two years, paid considerable attention to the treatment of resisting cases of club-foot. He had used the Thomas wrench without effect, but now, after having made some alterations in the osteoclast which he presented to this Association in 1892, he was able to exert sufficient force to produce fracture of the tarsus, which, he believes, is often necessary, and should be repeated at intervals, until resistance ceases, and the foot has assumed its normal shape and position. If the equinus persists, tenotomy of the tendo Achilles should be performed, and it is possible by this means, combined with osteo clasis of the tibia and fibula close to the ankle-joint, to permit the rotation of the foot upward, and to enable the patient to walk, on whom astragalectomy had failed to cure. Flat foot can be easily corrected by forcible instrumental rectification.

Mr. Edmund Owen, F.R.C.S., of London, said he had compared the old fashioned or orthodox treatment of club-foot with the radical operation of Phelps, and he preferred the latter method. While he had met with relapses from the older methods, such had not been the case since the employment of the free and open division of all constricting bands in the plantar region; and for the perfect correction of these deformities it was often necessary to open up the astragalo-scaphoid joint. The foot is forced into an over-corrected position, that of calcaneo-vulgus. The wound is treated openly, and a fixed plaster-of Paris dressing applied.

Dr. H. P. Kaptyn, of Abcande, Holland, was pleased with the results obtained from the open operation of Phelps; he had previously reported forty-two operations on thirty-two cases, to the International Congress at Berlin, of the cases in Holland treated after this method. In the newly born, he employed the fixed gypsum apparatus. The cases treated by the Phelps method ranged from nine months to fifteen years of age. Most of the cases were double. In no case, did he have to remove any of the tarsal bones, nor even open up the tarsal joint, as reposition of the foot was always possible after the contracted tissues were freely cut.

Excision of the Knee for the Relief of Crippling from Infantile Paralysis.—Dr. Ap Morgan Vance, of Louisville, Ky., said he had reported his first operation for the production of synostosis in 1885, it having been performed one year previously, to relieve the crippling from infantile paralysis. Since then he had performed the operation six times, making in all seven operations upon five patients. The two eldest patients, respectively five and seven years of age, died of some inflammatory complication of the heart, possibly endocarditis. The younger cases may be subjected to this treatment, with every possibility of success, but he does not advise the operation as late as eight or ten years of age.

Dr. A. M. Phelps, of New York, presented some modifications of his own splints, and of those of other surgeons, for knee and ankle joint diseases. The same author presented a new, improved celluloid corset. He said the apparatus combined neatness, elegance, durability, and lightness.

An Improved Machine for Treating Scoliosis.—Dr. Max Schede, of Hamburg, Germany, in a paper giving a

description of an apparatus, in which the patient was partially suspended, the shoulders and pelvis being fixed, advised that direct pressure be made over the ribs, over the most prominent part. He advised the placing of the patient in the apparatus, twice a day, for half an hour each time, and the application of as much pressure as could be borne with comfort. A good spinal support was worn during the interim; periodical measurements of the deformity should be made, so as to reckon the changes. Development of the muscles was also to be encouraged. In three months, the author claimed, appreciable improvement was often noted, in the most obstinate cases.

Infantile Apoplexy and Infantile Paralysis.—Mr. William J. Little, of London, suggested that copious, fatal apoplexy in the brain may occur during existence in utero, and that a lighter amount of apoplexy in a nerve-centre, at an earlier stage of uterine life, may be the cause of some of the anomalous conditions or congenital distortions, in which the growth and development of a limb had been interfered with. The author is of the opinion that the imbibing of alcohol in excess is the cause of the death of infants in utero, and says he recalls many instances of congenital distortions among the well-to-do, which have been produced by mental shock and mental trouble happening to the pregnant woman.

Treatment of Deformity Following Infantile and Spastic Paralysis.—Dr. De Forrest Willard, of Philadelphia, laid great stress upon the prevention of deformity, in the above class of cases, by means of apparatus. When contractures have occurred, it is necessary to resort to surgical measures before the apparatus is applied. Myotomy and tenotomy are perfectly safe operations, and the muscles are placed in better condition for action than they were before the operation. Forcible straightening, following division, is usually necessary. In spastic paralysis, lengthening of the tendons assists better locomotion. Locomotion is the best form of gymnastics.

An Original Operation for Wry neck.—Dr. A. M. Phelps, of New York, had devised an operation so as to prevent scarring, by beginning the incision at the lobe of the ear, which was carried upward, along and behind the ear, following the creases to its superior angle. The incision was carried directly across, into the hair, and extended obliquely downward, keeping within the hair line, to the side of the neck. This flap was retracted, and the offending sterno-cleido mastoid cut. Sometimes it was necessary to divide that muscle at its sternal end. The after-treatment was by a brace made of straps, attached to a plaster-of-Paris corset, together with gymnastic exercises.

Fixation in the Treatment of Fractures into Joints.—Dr. Ansel G. Cook, of Hartford, Conn., claimed that it has been conclusively proven, by experiments on men and animals, that fixation, *per se*, no matter how long continued, does not produce ankylosis; that ankylosis is the result of injury and consequent inflammation, and that early passive motion only irritates the injured structures and increases the production of callus, thus bringing about ankylosis. He thinks that immobilization is only useful when inflammation is present, or until the broken bones and ruptured ligaments have been mended. From three to eight weeks of immobilization is the time usually required. Lastly, passive motion, massage, and use, until the tissues become normal. Occasionally complete rupture of all adhesions, under an anæsthetic, is required.

Dr. Ryan said that passive motion should be employed as early as the sixteenth day.

Dr. Brackett asked Dr. Ryan if he had not been careful to regard the matter of pain produced by passive motion.

Dr. R. F. Weir, of New York did not believe in early passive motion in the case of fractures into joints.

Disease of the Shoulder joint.—Dr. W. R. Townsend, of New York, read a paper with the above title, in which he said out of 3,000 cases of joint diseases only 21 were diseases of the shoulder joint. The disease comes on more slowly in childhood than in adult life. Atrophy of the deltoid muscle may be so marked, in these cases, as to simulate paralysis. The sternal end of the clavicle is at times dislocated, while the shoulder-joint may be partially or completely ankylosed. Loss of function is one of the most prominent symptoms. The duration of the disease he considers to be from two to three years. The prognosis should be considered from the general condition of the patient and the local condition of the joint. The treatment may be by simple rest in a sling, or by fixation with plaster of Paris. The operative treatment may be partial or complete excision of the joint. Rarely is it advisable to excise the joint before the eighteenth year, up to which time partial arthrectomy is preferable, so that the growth of the bone will not be interfered with. The author did not think the statistics gathered before aseptic and antiseptic surgery were understood should be a criterion for our work of to-day.

Dr. Ketch said that Dr. Judson once read a paper on this subject, in which he explained its infrequency by the comparative freedom from injury and the blood-supply of the shoulder-joint. Dr. Ketch had not found ankylosis of such frequency as did Dr. Townsend.

Dr. Shaffer said he had an apparatus by which traction was made with an axillary crutch, and he does not think excision advisable, as his cases had usually gotten well without abscess. It is sometimes advisable to break up the adhesions under an anæsthetic.

Dr. John Ridlon said he had not seen any case which required excision, nor did any of them go on to ankylosis which would submit to mechanical treatment. He had used the traction splint of Shaffer in a considerable number of cases, but did not find that they did so well as when simple immobilization, without traction, was employed, while, on the contrary, in one or two cases, the pain had been increased by this traction splint.

The treatment which he employed was to bind the elbow to the side; supporting the hand by sling or "halter," and covering the shoulder, top and side, back and front, with two or three layers of stiff adhesive plaster.

Dr. Townsend, in closing, said that he felt all surgeons had to experience a period of radicalism in the treatment of joints, which resulted in more conservative views being taken. He wished to emphasize, however, the difference between the shoulder- and hip-joints. In the former, he considered it all important to have free movement, while in the latter a weak or frail joint is worse than one which is ankylosed.

Infantile Scorbutus in its Relation to Orthopædic Surgery.—Dr. Henry Ling Taylor, of New York, in a paper with the above title, said that infantile scorbutus, due to imperfect feeding, had lately attracted considerable attention, over seventy cases having been reported at a recent discussion of the New York Academy of Medicine. The disease, he said, is insidious in its onset and, unless recognized, may be fatal. The symptoms, some of which may be absent in any particular case, are: 1, a dusky pallor; 2, emaciation; 3, peevishness and general sensitiveness, which is often excessive; 4, exquisitely tender swellings, without local heat, near the joints of the lower extremities, due to subperiosteal hemorrhage; 5, inability to move the lower extremities and the trunk (pseudo-paralysis); 6, spongy or bleeding gums near the erupted teeth; and, most significant of all, 7, rapid improvement and cure on diet of fresh milk and orange-juice. The peri-articular swellings have been frequently mistaken for rheumatism, which may the more happen as fever may be present. A baby, a year old, was sent to the writer last summer, from the South, for treatment for a supposed spinal or hip affection. This baby had been fed on condensed milk, and presented a spinal projection at the upper lumbar region, with rigidity, in addition to the usual symptoms. The cachexia, spongy and bleeding gums, powerlessness of the legs, exquisite sensitiveness, and a swelling above the right

ankle made the diagnosis clear. All the symptoms disappeared, inside of three weeks, on a diet of Pasteurized milk and orange-juice. As other cases have been mistaken for hip-disease—osteitis of the knee, sarcoma of the knee, and infantile paralysis—it is particularly needful for orthopedists to bear in mind the possibility of scurvy, when differentiating infantile joint and paralytic affections. Discussion.

Dr. Ketch said that Dr. Jacobi, in discussing this subject, did not consider these so-called cases of pseudo-paralysis anything more than weakness.

Dr. Gillett reported a case, and said that he had found it difficult to distinguish it from rheumatism. His patient, however, was somewhat older than those being discussed.

Dr. Shaffer said that the differential diagnosis in scurvy at this age was from rachitis, Pott's disease, and rheumatism.

Dr. Ryan remarked that the late Dr. Knight, of the Hospital for Ruptured and Crippled of New York, had spoken of the scorbutic diathesis.

Dr. Taylor, in closing, said that he considered rachitis and scurvy to be different diseases.

The Association went into executive session, and the papers for the fourth day were read by title.

Election of Officers.—The officers elected for the ensuing year were as follows: *President*, Dr. John Ridlon, of Chicago; *First Vice President*, Dr. Bernard Bartow, of Buffalo, N. Y.; *Second Vice-President*, Dr. L. A. Weigel, of Rochester, N. Y.; *Secretary*, Dr. Royal Whitman, of New York; *Treasurer*, Dr. E. G. Brackett, of Boston.

Paralysis in a Telephone Employee.—Dr. Ewald reported at a recent meeting of the Berlin Medical Society the case of a young telephone operative who was just putting two subscribers in communication with each other, when she felt a violent shock and lost consciousness. When she came to herself she was found to have right hemiplegia, with contraction of the muscles on the right side of the face. The latter disappeared in a few days, and the paralysis of the arm gave place to tremor with ataxia; the paralysis of the lower extremity persisted longer, but was finally replaced by tremor. In the course of some months other nervous symptoms appeared, such as headache, vertigo, lumbar pains, trembling of the tongue, asthenia, etc. All measures looking to relief of these symptoms were ineffectual. The question arose whether the affection was hysterical in character, but none of the stigmata of hysteria could be found after a most careful examination. Inspection of the switch-board in the central telephone office showed that the operator, at the time of making the communication, may have become part of the circuit, receiving the full strength of forty volts.

The Value of Combining Heart-tonics.—Convallaria majalis is a simple cardiac tonic and a safe remedy. Its action is similar to that of digitalis, but not so marked. It causes slowing, and increases the force of the heart-beats. But it will frequently be found, in lessening compensation, that each of the foregoing drugs individually fails, and disappoints us after a time. Then a combination of all three often produces an effect little short of marvellous. Once or twice in recent years I have been called in consultation over cases of advanced mitral disease, in which central failure has shown itself by extensive dropsy of the limbs, œdema of the lungs and liver, and a general water-logged condition of the system. On inquiry of my colleagues in attendance as to the exhibition of digitalis, the reply has been, "He has had it." A similar response has been given in the cases of strophanthus and convallaria. But they had not been given collectively—and when this was done, benefit speedily accrued to the patient, and credit to his medical advisers.—Dr. Taylor, in *The Clinical Journal*.

American Medical Association.

Forty-fifth Annual Meeting, held in San Francisco, Cal., June 5, 6, 7, and 8, 1894.

(Continued from Vol. 45, page 799.)

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

First Day, Tuesday June 5th.

Suprapubic Hysterectomy.—Joseph Eastman, of Indianapolis, President of the Section, read the annual address, taking for his subject the operation of suprapubic hysterectomy. This operation, the speaker said, was original with him, and the method of procedure was illustrated by means of diagrams and instruments.

The method consists in tying the uterine arteries in the broad ligament close to the cornua of the uterus, and then peeling the peritoneum from the uterus, leaving the uterine arteries in the pelvis. The advantages claimed are the slight hemorrhage and the greatly diminished liability to septic infection by having no ligatures in the abdominal cavity. In closing the abdominal wound he said that the surgeon should expend greater efforts upon the proper suturing of the peritoneum than upon the external appearance, so that the wound will drain outward and not into the peritoneal cavity. He prophesied that in the near future the death-rate from the removal of fibroids will be reduced to an equality with that of the removal of ovarian cysts.

Operative Treatment of Fibroid Tumors of the Uterus.—Dr. Franklin H. Martin, of Chicago, then read a paper on this subject, in which he made a summary report of six previously published cases, and a first report of two recent cases, of his new operation for fibroids. Following are the conclusions of the paper:

1. In hysterectomy we have an operation which is bearing the test of time well; in selected cases in the hands of well-trained men it is the only absolute cure yet demonstrated for a certain class of fibroids.

2. The objections to hysterectomy as a cure for fibroids are the long training necessary to safely equip an abdominal surgeon for this most formidable of pelvic operations, the great death-rate of this operation in the hands of the tyro, the long prostration, accompanied frequently with nervous symptoms, following otherwise successful hysterectomies, its inapplicableness to extremely exsanguinated and otherwise reduced patients, and finally its inevitable death-rate of at least five per cent. in the hands of expert surgeons.

3. Removal of the appendages as an operation for fibroids is usually unsatisfactory, and should not be resorted to ordinarily, except as a last resort in a complicated case where the abdomen has been opened for the purpose of removing the uterus, and the latter operation for some reason has proved impracticable.

4. If the appendages are removed for the purpose of establishing an artificial menopause, and for the purpose of reducing small fibroids by modifying their nutrition, make sure to include in the ligature the main channel of the ovarian artery.

5. Vaginal ligation of the base of the broad ligament for fibroid of the uterus is an operation still on trial. As far as we have history of cases to back the theories of the operation it has stood the test.

6. Vaginal ligation of the broad ligament is a minor operation from the stand-point of mortality, and it is a minor operation from the stand-point of immediate and remote shock to the patient. It can be performed on any patient without risk, in almost any condition of physical prostration or weakness, so long as she is capable of taking an anæsthetic.

7. The operation is prompt in saving blood. It succeeds in cutting off one-third more blood to the uterus than does the Battey-Tait operation. Theoretically and practically it immediately checks uterine hemorrhages,

and at once begins the diminishing of the myoma by depriving it of its nourishment.

8. The operation of ligation of the broad ligament does not leave an abdominal scar, does not unsex the woman, as do both hysterectomy and the Battey-Tait operation.

9. There are no good reasons why ligation of the broad ligament should not be an early procedure in all conditions of uncomplicated fibroids of the uterus in which the operation is practicable, even though in a few cases, subsequently, a more radical operation might be necessary.

10. The operation of vaginal ligation of the broad ligament is practicable in all interstitial or moderately subperitoneal fibroids in which it is possible by careful dissection to expose the base of the broad ligament high enough to include in a ligature the uterine artery and its branches.

Dr. R. E. Horton, of Illinois, opened the discussion on the papers of the afternoon, saying that we must be guided in the selection of the method by the condition of the case. He commended Dr. Martin's operation for controlling hemorrhage and starving small fibroids.

Dr. McCall, of Michigan, spoke of the President's method as an ideal one, but thought that in many cases it could not be done. He recommended the conservative method of Dr. Martin, whenever applicable and spoke of the excellent results he had had with this operation. He thought that the failures in the operation of the removal of the appendages were largely due to the fact that the ligatures were not placed deep enough and close enough to the uterus. It is well even to include the cornu of the uterus itself.

Dr. Lapthorne Smith, of Montreal, followed with a plea for the trial of electricity before more radical meas ures are resorted to. He believed in using the positive galvanic current and constitutional treatment for two or three months, and if the case showed no improvement then, operate. Of the operations, he preferred Dr. Mar tin's, in which there was no death-rate, to that which in the best of hands gave a mortality of five per cent. Only in extreme cases should the graver operations be resorted to.

Dr. McMonagle, of San Francisco, summarized the dangers of fibroids of the uterus under the heads of hemorrhage, pressure, and malignant degeneration. With regard to Dr. Martin's operation, he inquired, "Will the degeneration be simple or malignant?" The operation, he felt, was still *sub judice*. He had had the misfortune to see electricity continued so long as to change a fibroid into a sarcoma. He also asked Dr. Martin, "What if the woman should become pregnant?" also if a starving of the uterus might not result in degeneration of mucous membrane and septic infection. He suggested that as a preliminary to the operation the uterus be curetted and stuffed.

Dr. H. O. Marcy, of Boston, said that he had never used electricity that the patient did not feel benefited by it. He has discarded its use for fibroids. If patient is young and tumor small it is best treated by ligation of the vessels and removal of the appendages. If the growth is larger, removal of the appendages may fail. He spoke of the extra-abdominal treatment of the stump as not being ideal surgery. It was still resorted to simply because the experience of older men taught it to be safe. If surgery is aseptic, nothing is gained by this method. We simply confess that we are afraid of hemorrhage and infection.

Dr. E. E. Montgomery, of Philadelphia, thought that the removal of so large a quantity of blood as in Dr. Martin's operation might cause degeneration, sloughing, and danger of sepsis. He feared that the use of electricity might produce malignant degeneration.

In reply to a question put to Dr. Marcy, he said he had never seen malignant degeneration follow the use of electricity.

Dr. Smith said, in response to inquiry, that he never employed galvano puncture, as it contained an element of danger, and the use of electricity should be free from danger. He thought that the cases in which electricity was charged with causing malignancy were errors of diagnosis. He instanced a case in which a supposed fibroid, not improving by electricity, was operated upon, when it proved to be a sarcoma of the ovary in which the uterus was embedded.

Dr. Martin, in closing the discussion, said he wished to eradicate an impression left on the minds of some not acquainted with him. He did not believe that his operation was applicable to all cases. When the case demanded it he was as ready to open the abdomen as anyone. He said he never knew a case of malignant degeneration to follow the use of electricity, but, on the contrary, a case of bleeding sarcoma, pronounced such by one of the most eminent pathologists in the United States, had been cured by him by this method. He called the attention of the Section to Dr. Byford's operation of hysterectomy as one of the best.

With regard to the results feared from cutting off the blood-supply in his operation, he said that in his first operation he was moved by the same fears, and it was the least successful of his cases because it was not sufficiently thorough. While perhaps two-thirds of the blood-supply is cut off, there is still more than the normal amount going to the uterus. He thinks that pregnancy can take place, and come to a successful termination, and hopes to demonstrate this in the near future. He stated that as a preliminary to his operation he always curetted the uterus, so as to make a clear field for his vaginal wounds.

Dr. Eastman showed that gangrenous masses existed in some of the specimens of fibroids that he exhibited. He asked Dr. Martin how he could tell that these did not exist before tying the broad ligament. All methods are not applicable to all cases. If any one method is applicable to all, it is that of enucleation. He thought that if it was necessary to drain through the vagina at all, cut widely upon a staff and pack the cervical canal, or insert a tube surrounded with gauze. He protested against a drainage that did not thoroughly drain. He thought the strongest point in favor of the abdominal fixation method of the stump was that there was one wound instead of two.

Second Day, Wednesday, June 6th.

Placenta Prævia.—Dr. Llewellyn Eliot, of Washington, D. C., sent a paper with this title, in which he designated placenta prævia, next to puerperal convulsions, the most serious complication that can occur in the lying-in chamber. The physician is usually not called until hemorrhage has appeared. No woman should be allowed to suffer from these hemorrhages if the child is viable, for it is as easy to resuscitate a child at seven months as it is a child at nine that has been subjected to the weakening effects of repeated hemorrhages. He considered the proper procedure to be to forcibly dilate, turn, and deliver, the child acting as a tampon in controlling the hemorrhage. He would hesitate to resort to Cæsarean section.

Dr. Eschlemann, of Fresno, said that placentæ prævіæ were much more common occurrences than generally supposed, a large number of abortions being of this character, it being nature's method of getting rid of them. He objected to the forcible dilatation and introduction of the hand for the performance of version. All that is necessary is to dilate the cervix sufficiently to introduce a small forceps, seize the head, and, using it as a tampon, bring it down and deliver the child. The os is usually very dilatable, particularly if the hemorrhage has been severe.

Dr. McChesney, of Philadelphia, said that in a case of placenta prævia there is no time for nice distinctions. One must use what means he can to dilate the cervix, turn, and deliver. In reply to a question from Dr. Whitney, of Oregon, as to the procedure in placenta prævia

centralis, he said the finger of the hand should be passed rapidly through the placental mass and then proceed as in a case of lateralis. Hemorrhage after delivery is checked by copious injections of hot water, massage, and ergot, or ergot and strychnine hypodermically or by the mouth.

Dr. Martin, of Chicago, said that it had been noticed formerly that fever had invariably followed the delivery of women in cases in which it had been necessary to introduce the hand into the uterus. We know now the cause of this. As much care should be taken in preparing the hands preliminary to introduction into the cervical canal and uterus as for a case of laparotomy. He recommended for this purpose saturated solution of permanganate of potash and oxalic acid, as used at Johns Hopkins.

Dr. Montgomery, of Philadelphia, believed that placenta prævia was the one condition in which the life of the child should not be considered. In central placenta prævia hemorrhage usually begins about the fifth month. The patient may have a fatal hemorrhage at any moment. As soon as the diagnosis is established, the uterine contents should be evacuated. When there is lateral implantation and the hemorrhage slight and later, we may temporize; but even in these cases it is well to bring on premature labor. The speaker did not think Cæsarean section necessary or advisable.

Dr. Newman, of Chicago, thought that dilatation, version, and delivery was the best and safest method. The case should be treated strictly on surgical principles. With regard to the use of an anæsthetic, he would hesitate to use chloroform after an extreme hemorrhage. He thought better work was done with the use of an anæsthetic, and ether was safe.

Dr. E. M. Westley, of California, has adopted different methods. If the patient is exsanguineous when the physician arrives, the life of the child cannot be considered. At once detach the placenta and bring it down; bring down the head of the child and deliver. If hemorrhage is slight and child alive, he preferred version before delivery.

Dr. Eshlemann, of California, emphasized the fact that in turning it was necessary to dilate the cervix to the size of the physician's hand, and run all the risk of septic infection. In introducing the forceps according to his method a dilatation of an inch was sufficient.

Dr. Carpenter, of Pennsylvania, reported that he had had three cases lately. In two he applied the forceps high up after getting head into position by external manipulation. He then brought the head down so as to compress the placenta, which had previously been pushed to one side. In one case he held the forceps in place one half hour before dilatation was accomplished. The patients were sustained by hypodermic injections of whiskey and strychnine. In the third case, one of central implantation, he found the patient moribund when he arrived. He tore through the placenta and found a foot, which he seized, and delivered the child as soon as possible. The patient died. With the hemorrhage controlled, the physician can afford to wait, and he believed that had he been less hurried in his procedure, and had improved the delay by the administration of proper stimulants he might have saved his patient.

Tetanus Puerperium.—Dr. Allison Maxwell, of Indianapolis, sent a paper with this title, in which he gave the clinical history of a case of this rare disease that had occurred recently in his practice. He reviewed the etiology of the disease and recommended in its treatment, besides prophylactic measures, the use of antispasmodics and antitoxines.

Dr. McChesney, of Philadelphia, in discussing this paper, said that the offending cause was some kind of dirt. The disease presupposed some kind of infection, and should have directed against it local treatment aimed toward its removal. He had had a case in which the initial symptoms of tetanus had appeared. He used an intra-uterine douche of a two-quart 1 to 3,000 bichloride solution, every eight hours, following this by water which had been recently boiled. He used at the same time hypodermic injections of peptonized milk.

Private Hospitals.—The President replied to some remarks made in the Surgical Section reflecting upon private hospitals and their owners. He said that the attack upon private hospitals struck at the very life of abdominal surgery. It was in a private hospital that it was born, nourished, and grew to full developed man hood. He resented the imputation that surgeons would be dishonest and use the private hospitals as a means of gain by retaining patients after the need of such retention had ceased.

Third Day, Thursday, June 7th.

Obstetrical Forceps.—Dr. Briggs, of Sacramento, read a paper on the "Function and Form of Obstetrical Forceps," using in demonstration instruments invented by himself.

Mrs. E. S. Meade, M. D., of San José, in discussing these forceps, said that they presented an anatomical defect, the pelvic curve was wanting. She thought the instrument too complicated. Great force was not necessary in delivering a child with instruments. She applied the forceps, used traction during pain, and readjusted the instruments as it might be necessary during the intervals of pain. Sometimes as long as half an hour would be necessary to accomplish the delivery. Too often physicians thought only of quick work without considering whether the mother and child were wounded. She considered that it was impatience and lack of anatomical knowledge that destroyed so many uteri and perinæums.

Dr. Oscar Mayer, of San Francisco, thought the complicated nature of the instruments was opposed to the principles of obstetrical asepsis.

Dr. Winterberg, of San Francisco, thought it a very easy matter to find an obstetrical case in which this and all other necessary instruments can be placed, and the whole thoroughly sterilized by subjecting to the necessary heat.

Dr. Brown, of Mendocino, Cal., objected to the forceps because they lacked the proper curve.

Dr. Briggs, in closing the discussion, said that the curve was greater than it seemed, being equal to three inches. It appeared less than this because the handle was parallel to the axes of the blade, while in the ordinary forceps it formed an angle.

Massage in Gynecology.—Dr. Oscar J. Mayer, of San Francisco, read a paper upon "Massage in Gynecology." He said the object of uterine massage is to bring about a healthier state of the circulation and to impart tone to the various structures of the genital tract. It is indicated in all disorders of chronic inflammation, as well as in such diseases as cause uterine displacements, produced by relaxation of the ligaments or by pelvic exudation, with or without adhesion. It is very important to form a correct diagnosis of the disease and to exclude all pyogenic disorders. The speaker then went into a description of the various methods employed and the indication for the employment of particular methods. The indications for massage in gynecology are the same as those for massage in surgery. He said, By massage treatment we wish to produce: 1. Acceleration of the absorption and retrogression of inflammatory and traumatic exudation and deposits. 2. Stretching, loosening, disintegrating, cicatricial, or hypertrophied connective tissues, caused by inflammatory processes. 3. Stimulation of the circulation and restoration of the normal elasticity and tone in (*a*) contracted, hardened, and hypertrophic tissues, or (*b*) relaxed tissues.

The sphere of usefulness may be tabulated as follows: 1. Pelvic exudations and hemorrhagic infiltrations. 2. Chronic parametritis and perimetritis. 3. Retroversio uteri. 4. Chronic metritis. 5. Prolapsus of the uterus and vagina.

Massage is contra-indicated in all diseases of the genital

tract requiring perfect rest of the whole body or of the genital tract alone.

The best and quickest cures from massage are observed in chronic diseases following the puerperal state. A longer time is required in diseases following acute inflammatory processes, also when coincident with anomalies of position of the pelvic organs, especially in retro derivations of the uterus. Even if we do not succeed in some cases in restoring the uterus to its exact normal position we can obtain a symptomatic cure without recourse to surgical procedure. The combination of massage with electricity is to be recommended in the relaxations of the supports of the uterus, provided the structures are intact.

By exercising proper circumspection we can often achieve more by alternating massage treatment with other treatments than by long-continued massage.

In conclusion, Dr. Mayer said that massage does not set up for itself the claim that it constitutes an independent and sufficient form of treatment. It is only a mechanical therapeutic agent, intended to be used in combination with other tried and accepted remedies in effecting a permanent cure, or in considerably lessening the time formerly required therefor. American gynecologists have been somewhat slow in accepting massage as a new remedial agent to be employed in diseases of women, and have been suspicious of the beneficial results that have been claimed for it. But the encouraging reports of European authorities, many of them erstwhile bitter opponents of massage, are favorable beyond the expectations of the most sanguine, and must work a change in this American sentiment.

Dr. J. H. Barbat, of San Francisco, bore testimony to the great good he had seen accomplished by massage, combined with electricity and glycerine tampons, even in cases when the removal of the ovaries had been recommended by competent physicians. He looked upon massage as one of the greatest remedial agents of the day.

Dr. Shuey, of Oakland, Cal., said that she had used massage in the painful menstruation of young women with the result of perfect relief from pain. They were cases of long standing, where none but medicinal treatment had been tried. She used the massage every day for three or four weeks, and during the menstrual period for three or four months afterward.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Twenty-eighth Annual Meeting, held at Lake Hopatcong, June 26 and 27, 1894.

John G. Ryerson, M.D., President, in the Chair.

Reports.—Dr. Stephen Pierson, Chairman of the Committee of Arrangements, read an interesting programme. The report of the Treasurer, Dr. Baldwin, showed a balance of over four thousand dollars. Dr. D. C. English said the Committee on Ethics had had nothing to do. The Committee on Honorary Membership made the following report:

The only name presented at the last meeting was that of our Recording Secretary, Dr. William Pierson, and in recommending him to the Society for election as honorary member, your committee take pleasure in referring to his twenty seven years' consecutive service, during which he has so faithfully and honorably discharged the arduous duties of that office; and although he was unanimously tendered the position of Third Vice-President by the Nominating Committee at the last session of this Society, he declined the honor, preferring to remain at his post and continue in the office over which he and his honored father have for over half a century presided.

A standing vote was taken, none voting in the negative.

The Health of New Jersey.—Dr. D. C. English read the report of the Standing Committee, which included an abstract of reports from physicians in the different parts of the State as to contagious and other diseases. It appeared the year had been a healthy one, there having been less of malaria, of diphtheria, scarlet fever, and other infectious diseases. In one or two places where diphtheria and typhoid had occurred, they had been traced to the milk-supply. Variola had been promptly suppressed, cholera had been kept out, the local health boards had shown more than usual activity. The organization in Essex County for a pure milk-supply had been successful, and promised to be of marked service in preventing the spread of tuberculosis, diphtheria, etc.

Prevention of Blindness.—Dr. W. B. Johnson read the report of the Committee on the Prevention of Blindness through Legislative Enactment. The movement to prevent blindness by legislative enactment had originated in New York State, and laws had been enacted in that State, and perhaps half a dozen others. They were based on the fact that blindness was due chiefly to contagious ophthalmia, and looked to the cure of this and prevention of its spread to others through use of towels, etc. The ophthalmia of the newly-born caused about ten per cent. of all cases of blindness, and made it imperative that the midwife should report cases at once in order that they might receive timely treatment, especially that known as Crede's by way of prophylaxis—washing the eyes immediately after delivery and dropping into them from the pipette two per cent. solution of nitrate of silver. On motion, the committee was continued and legislation urged.

Dr. William Perry Watson thought the license of midwives should be taken from them when they failed to report cases of ophthalmia neonatorum.

Report of Committee on Bovine Tuberculosis.—Dr. J. W. Stickler, Chairman of the Committee, made the report. He said the committee had supposed, when it went before the Legislature, that everybody was aware that tuberculosis existed in animals, and was likely to be transferred to man through milk and flesh. But they were mistaken, and were surprised to encounter not a little antagonism to legislation in the matter, and particularly against the bill which the committee had prepared as an efficient one; so that instead of adopting this bill another became law, which on account of its laxity would probably prove quite useless in the suppression of tuberculosis among cattle.

Dr. A. E. Conrow said it was necessary to have the co-operation of the farmers and the dairymen as far as possible, and therefore the bill which had been passed met with his approval until a more radical law could be enacted.

On motion the committee was continued, Dr. Conrow's name being added.

The Permanent Fund.—Since 1868 the Society had been accumulating a permanent fund, the interest on which, as the Treasurer, Dr. Baldwin, stated, was to be used for the publication of the yearly "Transactions." The sum had now risen to over four thousand dollars. Motions had been made from time to time to divert this fund to some other purpose, especially to the Society for the Widows and Orphans of Medical Men, which had no direct relations with the Medical Society. Dr. Ill had proposed a change in the by law, turning the amount of the permanent fund over to the society referred to, and making the members of the State Medical Society also members of the other. Drs. Skinner Lielbach, and others spoke eloquently in favor, while Dr. Baldwin took the lead in opposition. The change was rejected.

President's Address.—Dr. J. G. Ryerson, of Boonton, chose for the subject of his address, "Chronic Nephritis and Lactose." The following were some of the facts mentioned in relation to chronic nephritis, as leading up to the question of a special form of treatment, which in his experience had given remarkable results.

The profession generally, he said, did not realize fully the frequency of interstitial or cirrhotic kidney disease, nor its distinct pathology, its well-marked symptoms, its better prognosis under judicious treatment. In a fair amount of general practice Dr. Ryerson had, within a

little more than two years, met with thirty-three cases of chronic nephritis, twenty-nine of which he had diagnosed as cirrhotic. The diagnosis was frequently not made, because the symptoms were mistakenly attributed to disease of other organs, which, if affected at all, were affected only secondarily. Among the complications were heart disease, pulmonary disease, pleurisy, pneumonia, emphysema, bronchitis. The agents through which the different organs became affected was probably excess of one or more of the normal excretions of the kidney present in the blood. Increased action was demanded of the kidneys for its elimination, which called for increased force in circulation, the coats of the arteries in the kidneys became affected first, then elsewhere in the body. Incidentally, the President expressed disbelief in the view that men were more often affected than women, and that alcoholic drink was a common cause. His statistics pointed in the opposite direction.

Without considering the large number of symptoms he wound say that an increase in the quantity of urine with low specific gravity, pain in the head, loss of flesh and strength without apparent cause, were symptoms which should direct attention to the kidneys. If there should be frequent headache, palpitation and dyspnœa, general dulness, and disturbance of vision the diagnosis should be clear.

Dr. Ryerson had first used lactose in milk, and after learning that the beneficial effects were due to the lactose, he had during the past three years given this alone, and had found it much more efficient than in natural combination. This was a point on which stress was laid. He had now used lactose in 33 cases of chronic kidney disease in which he felt confident of his diagnosis, 30 having been cases of the cirrhotic kidney. Fourteen had previously been treated by other physicians, and in 11 the diagnosis had also been made previously. Emaciation was noticed in 27, insomnia in 28, dyspnœa in 24, pain in the head in 27, emphysema in 11, heart complications in 13, the urine was examined in 22, and albumin was found in 8, the average age was 53, males 13, females 20. Six patients had since died, and symptoms had returned after treatment in 7. He had also been furnished with notes of 13 cases treated by lactose by other physicians. In 36 cases of the total number lactose was the only treatment, in the others it was the only treatment of importance. Lactose was given in doses of from twenty to fifty grains. The average duration of the disease had been fifteen months. The points of interest in the treatment of chronic Bright's disease by lactose might be summed up as follows: Uniform certainty of effect; promptness of action; permanency of improvement; value in diagnosis; smallness of dose required; benefit not due to diuretic action; difference in effect of lactose taken in natural combination and taken as he recommended, in the free state. Forty three of the 46 cases were markedly benefited, all but 7 within three days. In 4 of the 7 in which the symptoms returned, relief was again obtained by lactose. In the 43 there was no return of the symptoms—so far as could be learned—within six months. In no cases was as much as three drachms of lactose prescribed in one day. The action of the remedy, he thought, lay beyond the kidneys, probably in the blood.

Erysipelas as a Complication in Abdominal Surgery.—Dr. George H. Balleray, of Paterson, described in this paper three cases of erysipelas, involving the abdominal wound, in patients operated upon by him some years ago, in the old building of the Paterson Hospital, the origin of the infection not being known, although two of the patients gave what might be called a history of predisposition to the disease. All recovered. Incidentally the author expressed preference for strict cleanliness in contradistinction to antisepsis during operations, and was apparently justified in his preference by the results of Mr. Bantock, compared with Mr. Thornton's, who worked in the same hospital.

Medico-legal Aspect of Abortion.—A committee was appointed upon this subject, consisting of Drs. Stickler, Baldwin, and C. A. Adams.

Observations on Cases of Movable Kidney.—Dr. H. G. Wetherill, in this paper, expressed preference for the incision parallel to the last rib, impressed the advantage of operating with the patient lying prone, cylindrical air-cushion under the abdomen to push up the kidney, gave preference to Dr. Edebohl's method of anchoring the kidney, and cautioned against the use of silk, lest abscess develop and lead to final destruction of the organ, if not to fatal sepsis.

The paper was discussed by Drs. Rogers, Chandler, and Balleray.

Angina Pectoris.—The subject for discussion presented at the last annual meeting related to angina pectoris, its true pathology, and an explanation of its sudden termination in death. The gentlemen who were to open the discussion were not present, but Dr. Baldwin related an interesting recent case of death in the first attack. The man had been in good health, ran violently some hundred feet, felt nauseated and faint, was assisted to his room, complained of pain and weight in both arms, and a feeling of depression, but there was no evidence of spasm. This was in the morning; he was relieved, but in the evening, while sitting up, he fell back dead. Post-mortem was not obtained. Dr. Baldwin thought obstruction of the coronary arteries had much to do with angina pectoris; also affection of the cardiac nerve supply, especially in sudden death.

Dr. Rogers and Dr. Cooper also made some remarks.

To Confer with the Pharmacists.—Delegates to corresponding societies presented their reports. Dr. Coit, who had attended the meeting of the New Jersey Pharmaceutical Society, offered a resolution, asking for the appointment of a committee of three to meet a like committee from the Pharmaceutical Society, to formulate some plan which might lead to more rational therapeutics and pharmacy.

Dr. Reynolds, of the Pharmaceutical Society, read a paper which went to show the necessity for closer relations between the pharmacist and physician, and between the two State Societies. The committee was appointed, and consisted of Drs. Coit, Silver, and Lewis.

Catarrh of the Upper Air-passages.—The Third Vice-president, Dr. T. J. Smith, read a somewhat exhaustive paper upon this subject. It was briefly discussed by Dr. W. B. Johnson.

The Code of Ethics.—Dr. George T. Welch, Chairman of the Committee appointed to consider the proposed revision of the Code of Ethics of the American Medical Association, said the committee had sent a circular to the district societies, and of eight which had replied before the recent meeting of the American Medical Association, six were in favor of the old Code, two thought it required modification. Since the American Medical Association had already taken action, sustaining the old Code, Dr. Welch hoped the report would be received without discussion and the committee discharged. His wish was granted by vote, but Dr. Barker asked, and finally obtained, consent to offer some resolutions re-affirming the Society's allegiance to the Code, and read a paper in argument therefor. The resolutions were almost unanimously adopted.

Action on the amendments to the by-laws, proposed at the last annual meeting, was deferred another year.

According to the report of the Committee on Prize Essays (prize of one hundred dollars), this Society, like many others, has to do much urging in order to bring out papers in competition. None had been offered in years.

Officers.—*President*, O. H. Sproul; *First Vice-President*, William Elmer; *Second Vice-President*, T. J. Smith; *Third Vice President*, D. C. English; *Recording Secretary*, William Pierson; *Corresponding Secretary*, E. L. A. Godfrey; *Treasurer*, Archibald Mercer; *Standing Committee*, H. W. Elmer, William H. Iszard, Henry Mitchell; *Committee of Arrangements*, G. E. Reading,

James Mercer, V. M. D. Marcy, L. M. Halsey, B. S. Lewis; *Business Committee*, H. R. Baldwin, W. B. Johnson, G. Van Wagenen, E. L. B. Godfrey, Updyke Selover.

Place of meeting, Cape May; time, June 25 and 26, 1895.

SECTION IN SURGERY.

First Day, Tuesday, June 5th.

Chairman's Address.—Dr. John B. Roberts, of Philadelphia, said that operative madness is rife in our day. This madness is endemic among those whose preliminary training has been deficient. Preliminary education is a corrective, and a reaction is fast taking place. A true surgeon, possessed of a thorough pathological knowledge, must be a man of broad culture and have had an adequate preliminary education. Surgeons should be careful to make accurate statements and to refrain from criticising others. A great surgical sin is the overlooking of the influence of the nervous system upon disease. The speaker condemned the evil of physicians controlling private hospitals. Such an institution is a hotel for patients, and of course those interested are tempted to strive to keep it filled with long-staying guests. The sin of charging large fees was also condemned. A man who refuses his counsel to a brother practitioner because the patient is poor, commits another sin, as also does the one who charges for services rendered to a physician or his family. The use of secret nostrums was denounced as unscientific.

Malignant Neoplasms from a Micro-technical Standpoint.—Dr. A. P. Ohlmacher, of Chicago, said that many things are described as cancer parasites because this subject has been handled unscientifically. A great number of reagents have been used, hence the diversity of results, since artificial products are formed by the reagents. It has been found that sporozoa treated by different fixing solutions act differently. Some agents distorted the spores and interfered with the subsequent staining. All the present methods of investigation are faulty, and no results are to be looked for until new methods are devised.

Early Surgical Interference in Malignant Tumors.—Dr. R. A. McLean, of San Francisco, Cal., said that malignancy once established, removal must be immediate. Recurrence is frequent because the laity delay until the case is hopeless.

The causes of failure in operation are: The size of the growth, infiltration, metastases, ulceration, exhaustion, and septicæmia. The great mistake is in not insisting on a radical operation. A temporizing policy is fatal. In suspected cases, carcinosis, tuberculosis, and syphilis are to be differentiated. Early in the case a small operation only is, as a rule, necessary. In operating take out as much as possible with safety, go well around the probable limits of infiltration. In carcinoma of the tongue or lip, take out the bone if eroded. In the extremities, amputate on the proximal side of the next articulation above the growth. Excision should be practised in all cases where general health is good.

The Value of Caustics in Malignant Growths.—Dr. John Parmenter, of Buffalo, said that many claims are made for caustics, to wit: That after their use recurrence is less frequent, that the various agents of this kind have a selective action, and that we may obtain a reduction in size of the enlarged lymphatics. These claims are not well grounded. The value of caustic lies in the selection of a proper agent and the selection of proper cases. A proper caustic is one which entirely destroys the diseased tissue, and it should be rapid in its action. Caustics must be used in conjunction with common-sense. Burn all the diseased tissue. Don't spread over too extensive a surface. Mitigate as much as possible the pain. Suitable cases are those located in a favorable anatomical situation, and those in which there is no involvement of the ymphatic glands.

Dr. L. Duncan Bulkley, of New York, said that caustics are used by quacks, still they have their use. They are indicated in (1) the early stages, and are useless after metastases, extensive ulceration, or glandular involvement have taken place. (2) In the formative period. (3) In epitheliomata in accessible regions.

The best form of caustic is a mixture of wheat flour, arsenic, cinnabar, ammonia muriate, mercury bichloride, and zinc chloride. Mild caustics are useless, and silver nitrate is of no value whatever.

Pyrogallic acid is serviceable after curetting.

The Radical Cure of Malignant Tumors by Operation.—Dr. J. H. Wythe, of Oakland, said that cancer is often removed as a palliative measure. Cure by removal can follow only when the growth is of local origin. Persistent removal after recurrence is often followed by permanent cure. Two principles are to be observed, namely, operate early, and remove a quantity of the neighboring tissue with the growth.

Dr. Morrison said that general practitioners should be able to recognize and also treat malignant growths. Caustics are useless, and we should always use the knife.

Dr. Shiels, referring to Dr. McLean's paper as regards differentiating between syphilis and malignancy by treatment, said it was not always possible, because some forms of gummata yield neither to iodides nor mercury.

Dr. Griswold, of Pennsylvania, recited a case where he operated simply to prolong life. Caustics should be used only when the patient positively refuses surgical measures.

Dr. Plane, of Michigan, thought that there was no means of making a prognosis in a large class of tumors.

Dr. J. W. Cottenhauer, of Iowa, made the claim that malignant tumors are never cured.

Dr. Bulkley, of New York, said caustics as commonly used are dangerous. He believed that a simple growth might be made malignant by the irritation of caustics.

Dr. Bishop, of Pennsylvania, appealed to the Section to take a decided stand in regard to caustics. We should never allow the patient to select the method of treatment.

Second Day, Wednesday, June 6th.

Discussion on Tubercular Joint Disease.—Dr. Emmet Rixford gave briefly the symptoms which are to be depended upon in the early recognition of this disease.

Dr. R. H. Sayre, of New York, laid much stress on the manner of applying the plaster cast in the treatment of joint disease. Interest was added to the paper by photographs displayed to illustrate the various methods.

Dr. S. Stillman, of San Francisco, followed with a paper on the "Treatment of Tubercular Joints by the Injection of Iodoform." He dwelt on the technique of the operation and on the location of the tubercular foci.

Concussion of the Brain.—Dr. L. C. Lane, of San Francisco, read a paper on this subject. After reviewing the history of the subject and giving a general *résumé* of the various theories brought forward in regard to the subject since 1840, he went on to explain why in most cases the diagnosis was easy, whereas in other cases most difficult, especially where there was no history of a blow or a fall upon the head.

He divided the cases into three general classes or grades: 1, The mild; 2, severe; and 3, the fatal cases.

As symptoms of the trouble he enumerated vertigo, faintness, weakness, drowsiness, and coma. The prognosis was dependent on the extent of the injury. As after-effects in some cases, he mentioned melancholia and mania.

Treatment of Fractures of the Lower End of the Humerus.—Dr. Allis sent a paper with this title. The main point brought out was the advantages to be derived from treating such injuries with the arm in extension and the patient in the recumbent posture. This facilitates the circulation of the blood, the examination of the part, and the renewal of the applied dressing.

Passive motion he said was only to be used in the latter half of the treatment. A lengthy discussion then followed, which was represented on the one side by Dr. Lane, who favored the method employed by Allis, and on the other side by Dr. Sayre, who favored the rectangular position.

Discussion on Hernia.—Dr. J. Ransohoff, of Cincinnati, O., emphasized the great importance of immediate operative interference in the case of the strangulated hernia, and the great danger to be apprehended from prolonged taxis which has a tendency to decrease the vitality of the gut, as well as to make the subsequent operative procedure less favorable in its results.

Dr. A. E Rockey, of Portland, Ore., then followed with a paper entitled "Observations on the Radical Cure of Inguinal Hernia." He advocated the idea of operative interference also in many cases of long standing and in cases where the hernia is very large.

Dr. H. O. Marcy, of Boston, advocated the use of kangaroo tendon in suturing, in preference to catgut. A lively discussion followed, which showed that there are still many adherents to the conservative method of treatment.

A Plea for the Better Teaching of Anatomy.—Dr. Schiel read a paper with this title, in which he said that among all medical studies, anatomy probably ranked first in importance. The lack of interest shown by students in the study of anatomy was, he thought, largely due to the methods of teaching. He also laid great stress on the evil results consequent upon a deficient education in this branch of medical science. These, he said, were not only meted out to the physician, but also to the patient, who falling into the hands of a practitioner with only a superficial knowledge of anatomy was like a lamb being led to the slaughter, unconscious of the danger which awaits him.

Third Day, Thursday, June 7th.

Symptoms and Treatment of Tumors of the Bladder.—Dr. C. F. Buckley, of San Francisco, read a paper which was mainly a detailed account of three cases of tumors of the bladder, produced in these patients undoubtedly by traumatisms of the perinæum. He indicated that in his opinion not enough attention was paid to injuries of this sort. Dr. Buckley also exhibited a slate pencil removed from the bladder of a male subject by the median operation; and a collection of gall-stones removed from the gall-bladder of a patient during life.

Pathology and Symptomology of Hemorrhoids, Anal Fistulæ, and Anal Fissure.—Dr. David Powell, of Marysville, Cal., read a paper with this title. Clinically he divided piles into external and internal, although their pathology is the same. The veins involved are the inferior and superior hemorrhoidal plexus. In their initial stage they are nothing more than dilated rectal veins. Later, characteristic changes take place and the tumor enlarges. As causes he enumerated fecal accumulations, the gravid uterus, or some obstruction to the hepatic circulation. The internal he classified into: 1, venous; 2, arterio-venous; and 3, the capillary. The speaker next took up the subject of anal fistula. This usually originates in an ulcer. It may also be caused by a thrombosis or tubercular foci which induces suppuration. This trouble he said was often not accompanied by any urgent symptoms.

The subject of anal fissure was next discussed. This, the speaker said, was a most important subject practically, not because of its pathology but rather because of the pain and annoyance which invariably accompany it. Among the characteristic symptoms he mentioned: Dull aching pain, aggravated by evacuation of the bowel. Morning diarrhœa, loss of blood, continual irritation of the genito urinary organs, and tender prostate. The constitutional disturbances are often marked. If trouble is unrelieved, patient becomes pale, anxious, and looks careworn.

Dr G. B. Somers, of San Francisco, said the treatment of anal fistula was by no means always a simple one on account of two complications: 1, cicatricial tissue was frequently found in the canal; and 2, collateral sinuses often existed, hindering the surgeon in his work. In most cases the fistula is preceded by an abscess, which may be either pyogenic or tubercular in origin, which imparts to the fistula its characteristic aspect.

Methods of treatment are mainly four: 1, by injection; 2, by ligation; 3, by Mathew's fistulatome; and 4, the radical operation by the knife. Dilatation of the sphincter, he said, should always precede the operation.

Dr. Thomas W. Huntington, of Sacramento, stated that anal fissure, though more common between the ages of twenty and thirty five, occurs at times during infantile life and in old age. It occurs as often in men as it does in women, a view not generally held up to this time.

The symptoms are morning diarrhœa, tenesmus, intense paroxysmal paralyzing pain quite out of proportion to the size of the ulcer.

There are two general methods of cure: 1, by dilatation of the sphincter; and 2, by incision. Incision always to be done under anæsthesia. The speaker favored the combined plan of incision and dilatation.

Treatment of Stricture of the Urethra.—Dr. Rosenstein gave briefly his experience with the employment of gradual dilatation and internal urethrotomy. In summing up he stated that he decidedly favored gradual dilatation, and that in his opinion internal urethrotomy will eventually be abandoned because of the dangers associated with the operation, and because, in his opinion, the cure after urethrotomy was not any more permanent than after gradual dilatation.

A lively and very interesting discussion now ensued.

Dr. Thomas, of Pennsylvania, said that in certain cases he decidedly favored internal urethrotomy, in others divulsion.

Dr. Huntington, of California, remarked that he rather favored internal urethrotomy, as gradual dilatation did not always cure the discharge.

Dr. Dodge, of Michigan, said he had seen worse reaction from the use of the sound than from internal urethrotomy.

A number of other physicians gave their opinions, by which it seemed to be the consensus of most present that internal urethrotomy was well adapted in many cases, and that it will always occupy a place in surgery.

It also was thought by many that the cure of stricture is not a permanent one, and that sounds have to be used at shorter or longer intervals to keep the stricture from again contracting.

Fourth Day, Friday, June 8th.

New Plastic Operation for Varicocele.—Dr. O. J. Mayer, of San Francisco, read the paper. The feature of the operation is the transverse suturing of the longitudinal wound, which method considerably shortens the scrotum. A case which had been operated on was presented.

Dr. Mayer then read a paper on a "Bloodless Vaginal Myectomy." The essential step in the operation being the temporary ligation of the uterine arteries.

Acetanilid in Medicine and Surgery.—Dr. G. W. Woods, of the United States Navy, Mare Island, California, read a paper in which he gave a brief account of the preparation and composition of acetanilid. Antifebrin, he said, was simply another name for acetanilid. It is a good antipyretic and not poisonous if given in small doses at the commencement, even to children. It acts slowly and is both a diaphoretic and diuretic. It may be given in any and all fevers and inflammations. It is a good substitute for iodoform in venereal sores. The only thing experienced on its application to a granulating surface is a burning sensation, which, however, persists only a short time. It is useful in the dressing of all forms of burns, ulcers, moist eczema, gunshot wounds, abscesses, etc. When applied to extensive granulating surfaces it sometimes pro-

duces cyanosis, which is not due to a disturbance of circulation, but to a deficient oxygenation of the blood. To sum up, the speaker said, acetanilid is exceedingly useful because it is cleanly, odorless, antiseptic, desiccating, practically non-toxic, does not crust, is easily removed, insignificant cost, not altered by moisture.

Contagious Period of Syphilis.—Dr. Thomas, of Pennsylvania, emphasized the fact that he was perfectly convinced that syphilis is only contagious in the primary and secondary stages, that is only for three to four years after the primary lesion.

Dr. Schiels reported a case of multiple, symmetrical, bilateral lipomata. The lipomata were not limited to any particular part of the body, but occupied positions from the neck down to the groin.

The Surgical Engine.—Dr. Bonnwell, of Philadelphia, Penn., then read a paper on this engine, which was, he said, very similar to the ordinary dental engine. It caused the trephine or burr to revolve from a hundred to twenty thousand times a minute. It is said to be adapted to the performance of all sorts of surgical operations, on both the soft parts and bony tissue.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 14, 1894.

George C. Freeborn, M.D., President, in the Chair.

Rupture of the Liver.—Dr. E. Hodenpyl presented the specimen. There was extensive laceration of the organ due to an injury, yet death did not occur for three weeks, and was then due to peritonitis and septic infection. The patient was said to have had a kick from a horse, yet he received practically no attention until about three weeks later, when he reached the hospital after a ride in a street-car and a short walk. He was much exhausted at the time of admission, and died two hours later. At the autopsy the body was found to be emaciated. There was no external sign of injury, and no fracture of the ribs or vertebræ. There was an intense peritonitis with connective tissue bands uniting the coils of intestine. Behind the intestine, on either side of the vertebral column, were two large collections of stinking blood—at least two quarts on either side. The whole of the right lateral border of the liver was torn away, and the right lobe was exceedingly friable, so that a dull probe could be inserted into the liver tissue for at least six inches. The fact that the man survived the injury so long was very remarkable, for most cases of rupture of the liver prove fatal within a few hours, from hemorrhage.

Sub-phrenic Abscess.—Dr. Hodenpyl also presented a specimen of sub phrenic abscess. It had apparently resulted from a perforation of the gall-bladder. The subject was a man twenty-three years of age, who had been excessively intemperate. In the winter of 1892 he had severe colicky pains in the region of the umbilicus, lasting for three weeks. The present illness began on December 10th, with a nearly constant pain referred to the umbilicus and upper abdominal region. Two days later he noticed the abdomen beginning to swell, and ever since then it had steadily increased in size. On admission he was well nourished, and very slightly jaundiced. There was some swelling of the feet and limbs; the abdomen was considerably distended, but there was no fluctuation; the temperature was 100° F.; pulse, 112; respirations, 24; urine normal. Physical examination showed flatness over the lower part of the right lung, beginning at the third space, and some dulness posteriorly over the left lung. The heart was normal; splenic dulness not increased. On December 22d paracentesis abdominis was performed, and 166 ounces of slightly turbid reddish brown fluid were withdrawn. This gave marked though temporary relief. On December 25th a needle was inserted into the right chest posteriorly and some bloody serum drawn off, and on the following day paracentesis was again performed. Some reddish-brown fluid was evacuated, and this gave a distinct bile reaction. On December 27th a four-inch vertical incision in the right lumbar region was made, about the level of the umbilicus, and on cutting through the abdominal muscles and peritoneum about two and a half litres of clear brownish fluid escaped. The incision was enlarged and disclosed a cavity of considerable size. There was a well marked line binding together the intestines and separating them from the peritoneal cavity. In the upper part of the incision was a rounded cicatrix half an inch in diameter. The wound was packed. After two days the patient developed diarrhœa with some blood in the stools, and on January 16th he died. No complete autopsy was permitted, but the liver was removed through the abdominal wound. Over the whole right lobe, posteriorly, was a large collection of fibrin and pus immediately beneath the diaphragm. Over the whole lower lobe of the right lung was a rather thick coating of fibrin and pus. There was an intense peritonitis with organized adhesions. The gall-bladder showed a circular opening about the size of the little finger with rounded edges. This might have been ante-mortem or due to the necessarily forcible extraction of the liver.

The speaker said that in most of the cases of sub phrenic abscess that had been reported, the condition was due to the extension of a pleuritis, but in this he thought it was rather due to rupture of the gall-bladder.

Carcinoma of the Stomach.—Dr. Hodenpyl next presented a specimen of the above. It was removed from a man, fifty years of age, who had suffered for a number of years with phthisis. For the last year of his life there were marked gastric symptoms, particularly vomiting of "coffee-ground" material. He was so much emaciated that the tumor could be easily felt on palpation of the abdomen. There was not much stricture of the pylorus, but just above this point was an ulcer one and one-half inch in diameter and one inch deep. There were several large capillaries in the base of this ulcer, from which the hemorrhage probably occurred.

Dr. George P. Biggs said that last spring he had presented to the Society a specimen not unlike the one of sub phrenic abscess just exhibited. In his specimen there was a large calculus having the shape of the interior of the gall-bladder, and lodged in the common and hepatic ducts. There was one quite large ulcer and several small ones in the fundus of the gall-bladder, and several collections of pus around the gall-bladder with perforation into the pleural cavity.

Sarcoma of the Tongue.—Dr. E. K. Dunham presented this. It had been removed by operation, by Dr. Joseph D. Bryant, from a man sixty-one years of age, whose family history was negative, except that several of the members of the family had died of tuberculosis. The man was somewhat alcoholic in his habits, and was accustomed to smoke ten pipes of tobacco a day, using a briar-wood pipe. About eight months ago he bit his tongue on the right side, one inch from the tip, causing a blister, which by contact with a rough tooth became irritated. A tumor slowly grew on this spot, and when first seen was three-fourths of an inch in diameter. On microscopical examination the structure of the tumor appeared to be that of a large round-cell sarcoma. The speaker said that the literature of the subject was very meagre. Max Schreier, in the *Klinische Wochenschrift* for June, 1892, reported several cases. He also recorded two cases in which there was an anatomical diagnosis of sarcoma of the tongue, but in which no clinical history was obtainable. In the cases which he cited the majority were at the back of the tongue, and most of them were either small round cell, spindle-cell, mixed-cell, or lympho-sarcomata. The only large round cell sarcoma reported was one by Mercier in 1890, situated near the tip of the tongue on its dorsal surface. It was a fungous growth attached to the tongue by a thick pedicle, and was made up of large round cells, some of which were multi nucleated, with a small amount of intercellular stroma which could be more or less distinctly traced from the connective tissue surrounding the tumor. In that

case, as in the one just presented, there was no ulceration around the tumor; the epithelium was intact, and showed no tendency to involve the underlying tissues.

Dr. T. M. Prudden said that the specimen seemed to be undoubtedly one of sarcoma, perhaps of the kind sometimes called angio-sarcoma. He had seen three or four small sarcomata of the tongue, all of the spindle-cell or small round-cell variety. The specimen exhibited under the microscope was so beautiful, he would like to ask how it had been hardened.

Dr. Dunham replied that the whole tumor was first hardened in a saturated solution of bichloride for five hours; then in seventy per cent. alcohol containing some iodide of potassium, and then successively in eighty per cent., ninety-five per cent., and absolute alcohol. The section was cut in paraffin.

Typhoid Fever with Extensive Ulceration.—Dr. George P. Biggs presented a supplementary report on the case of typhoid fever with extensive ulceration of the cæcum which he had presented some time ago to the Society. Cultures from the spleen showed bacilli possessing all the morphological and biological characters of typhoid bacilli, including the growth on potato. Cultures from the peritoneal exudate showed the streptococcus pyogenes very abundant, with bacilli which had apparently the characteristics of the colon bacillus, including the development of bubbles of gas in cane sugar bouillon.

Pulmonary Thrombosis and Infarctions.—Dr. George P. Biggs also presented a supplementary report on this recent case. It was one of dilated heart with multiple pulmonary thrombi and infarctions. The areas in the lung showed the ordinary structure of hemorrhagic infarctions, and branches of many of the pulmonary arteries showed distinct endarteritis. The lesion most frequently seen in the sections was a fibrous thickening of the intima with slight narrowing of the lumen; distinct obliterating endarteritis was occasionally seen. The media and adventitia of some of the vessels contained a few small round cells. The vessels of the liver and kidneys appeared to be normal. It was rather interesting to note the absence of any gross evidence of arterial disease, and the evidence microscopically of slight, but distinct, changes apparently limited to the pulmonary arteries. The arterial disease, with the marked enfeeblement of the circulation present in the case, fully accounted for the thrombi, and apparently for their presence only in the lung.

In connection with that case the speaker reported one presenting very similar lesions. A woman, forty years of age, had had for several years more or less palpitation, dyspnœa, and œdema of the legs. She had never had rheumatism. Five months before death she had severe headache, cough, vomiting, dyspnœa, and dimness of vision, soon followed by œdema of the feet. The urine became scanty and high-colored. On admission, the temperature was 101° F., respirations, 40, and the pulse, 108; there were many subcrepitant râles over the lung posteriorly. The apex beat was in the fifth space, 5½ inches to the left of the median line. A faint systolic murmur was heard at the apex; the heart action was regular and of fair force, and the pulse had a high tension. The liver extended from the fifth space to the level of the umbilicus. A moderate quantity of fluid was detected in the peritoneal cavity, and there was marked œdema of the lower extremities. Examination of the urine showed it to have a specific gravity of 1.014, and to contain from ten to twenty per cent. of albumin, with many casts. Twenty to twenty-five ounces of urine were voided daily. She was under observation in the New York Hospital for two months, during which time the dyspnœa, vomiting, headache, and scanty urine were the prominent symptoms. During the last ten days of her sickness there was cough with moderate bloody expectoration. At the autopsy it was noted that she was an extremely obese subject, the fat in the abdominal walls being 7 ctm. in thickness. Many old pleuritic adhesions were found, and also a moderate increase in the pericardial fluid. The heart was considerably hypertrophied, but predominantly dilated. All the cavities were distended with post-mortem clots; all the valves were normal; the muscular substance was pale, but fairly firm. The coronary arteries and the aorta were slightly atheromatous. There was a thin thrombus, 1 ctm. in diameter, at the junction of the transverse and descending portions of the arch of the aorta. There were no ante-mortem thrombi in the heart itself. In the left lung ante-mortem thrombi were found in many of the larger branches of the pulmonary artery in both lobes. Many of these thrombi nearly occluded the vessels, but there were no infarctions except two small ones in the anterior border of the base, 1½ ctm. in diameter. In the right lung there were large thrombi in the main subdivisions of the pulmonary artery, and multiple small infarctions scattered through the upper and lower lobes. The largest, which was in the posterior part of the lower lobe, measured 4 ctm. in diameter. The lungs were generally congested and œdematous. In the common iliac and femoral veins were large thrombi apparently completely occluding the vessels. The kidneys showed advanced chronic diffuse nephritis. It was quite possible that some of the infarctions came from emboli in the femoral vessels.

Typhus or Typhoid Fever?—Dr. George P. Biggs then presented specimens from a case seen first at the Reception Hospital, and then at the Riverside Hospital. The patient was an Austrian, twenty one years of age, who when admitted to the Reception Hospital had a temperature of 105° F., with a moderately profuse eruption which was regarded as that of typhus fever. He said he had been sick for three days. The patient was under observation for eighteen days, and the history was furnished by Dr. S. D. Hubbard, of the Riverside Hospital. The temperature for the first three days was between 105° and 106° F., and, during the following eleven days, it ranged between 106° and 103°, the average being 105° F. During the last four days it fell gradually from 103° to 100°, the average being 102° F. His pulse for the corresponding periods was 120 to 124, then 100, then 80, and during the last few days 124. The respirations varied between 26 and 36 during the entire time. Low, muttering delirium was noted on the sixth day of the disease, and was frequently present throughout the course of the disease, especially at night. The eruption was at first macular, but by the ninth day it became petechial. The countenance was dull and dusky, and the eyes were congested. The spleen was enlarged throughout the course of the disease. There were signs of obstruction of the dorsalis pedis artery two days before death. At the autopsy it was noted that he was extremely emaciated, and that rigor mortis was well marked. The toes of the left foot were of a pinkish-red color, owing to the obstruction of the artery. The serous membranes were all normal. The heart was distended with post-mortem clots. Attached to the inner surface of the lower half of the anterior wall of the left ventricle were many firm grayish ante-mortem clots, forming a mass about the size of a hen's egg. The ventricular wall corresponding to the attachment of these thrombi was only 1 ctm. in thickness, while at the base it was 2 ctm. thick. There seemed to be no explanation for these variations in thickness of the wall. The muscular substance was pale and moderately soft. The valves were all normal. No ante-mortem clots were found in the heart, except in the left ventricle. The coronary arteries and aorta were very slightly atheromatous. The lungs showed marked bronchitis, but no thrombi or infarctions. The spleen was about four times its normal size, was of a dark-red color, and contained an infarction in the posterior portion, 4 ctm. in diameter, and two others in the anterior portion, somewhat smaller. The mesenteric glands were distinctly enlarged, measuring 1 to 1½ ctm. in diameter. The kidneys were excessively anæmic, and their parenchyma degenerated. In the left one was an infarction, 4 ctm. in diameter. The

liver was soft and pale. The mucous membrane of the whole ileum was moderately congested; Peyer's patches were unusually distinct, with a finely granular surface; some of them were slightly elevated and presented a few points of superficial ulceration, two to three mm. in diameter. The colon appeared to be normal. The brain showed marked atrophy of the convolutions, with corresponding increase of the fluid in the pia.

The cause of death in this case appeared to be a cardiac thrombus with resulting multiple embolism occurring as a complication of some acute infectious disease. It was diagnosticated clinically as typhus fever. The speaker said he thought the lesions pointed rather to typhoid than to typhus. The points in favor of typhoid fever were, first, the distinct enlargement of the mesenteric glands, which were not usually enlarged in typhus fever: and secondly, the distinct but slight lesion of Peyer's patches. There was no characteristic lesion of these patches, unless possibly the "shaven beard" appearance. Regarding the case as one of typhoid fever, it would be in the fourth week at least. The most reliable statistics placed the average duration of typhoid fever at twenty-four to twenty eight days. In the fourth week, therefore, if the disease had progressed favorably, one would expect to find varying degrees of healing of the ulcerated Peyer's patches, and this seemed to be the condition in the specimens presented.

In this connection the speaker presented specimens from a recognized case of typhoid fever on the twenty-third day of the attack. The patient was a male, thirty-five years of age, in whom the disease ran a perfectly characteristic course for four weeks. The temperature remained nearly at the normal for about three days; then it rose again and continued high for twenty-three days, when he died of multiple pulmonary thrombi with infarctions. The autopsy in this case showed the heart considerably dilated and flabby, without thrombi. There was an infarction in the anterior border of the right base, about one inch in diameter, and four smaller ones in the left lower lobe. In addition there were many thrombi of the size of a split pea in both lungs, at the bifurcation of the pulmonary arteries. They encroached only moderately on the lumen of the vessels. The spleen was twice the normal size, of a deep red color, and moderately soft. The mesenteric glands were moderately enlarged. The kidneys showed parenchymatous degeneration. The liver was soft and pale. The intestines were heavily coated with mucus, but appeared otherwise normal, except in the lower portion of the ileum, where the Peyer's patches were slightly pigmented and presented a finely granular surface. The colon showed a few pigmented points, probably healed ulcerations, and a few superficial ulcerations not yet healed.

The pathological conditions in these two cases were very similar, yet the clinical history of the first case resembled that of typhus, while that of the second case corresponded with that of typhoid fever. In the first case death occurred about the beginning of the fourth week, or possibly later; in the second case death occurred at the beginning of the fourth week of the relapse. In both the intestines have evidence of lesions of Peyer's patches undergoing repair, and also of a slight enlargement of the mesenteric glands, and decided enlargement of the spleen. The cultures from the spleen in the first case developed nothing which could be regarded as at all characteristic of typhoid; in the second case cultures were not made.

Sarcoma of the Face.—Dr. J. E. Weeks presented this. Tumor was removed from the face of a man aged sixty five. About thirty years ago he had noticed a small tumor on the side of the nose, which, after some years, presented a small ulceration. This tumor was removed in 1870. About twelve years later, the cicatrix became congested and the tumor recurred. The patient then came under the care of Dr. Derby, who found the growth on the left side of the bridge of the nose, near the inner canthus, adherent to the subjacent tissue, and separated from the canthus by a half inch strip of healthy skin. It was nodular, irregular, and elevated, and on removal exposed a bleeding surface. There was no enlargement of the pre auricular gland on that side. The tumor was referred to the speaker for examination. The posterior surface of the tumor was covered with degenerated epithelium, and consisted chiefly of irregularly cylindrical and club-shaped hyaline, homogeneous masses, which took eosin stain like connective tissue. There were small collections of epithelial cells between the hyaline cylinders, which penetrated to a considerable depth. Pymphoid cells were quite numerous, and in some places were seen in the centre of the hyaline masses. There was a scanty connective-tissue framework in nearly all parts of the growth. The blood-vessels were not found in the centres of the hyaline masses, but were quite plentiful on the periphery. The walls of the arteries in the centre of the hyaline masses were thickened and degenerated, and there were extensive extravasations of red corpuscles and blood pigment throughout the growth, indicating profound vascular changes. This form of tumor, the speaker said, had been classified as sarcoma. Billroth described a similar tumor in 1866, which he termed a "cylindroma." This variety of new-growth was most frequently met with on the face, although it had been found at the margin of the anus. Out of twenty-four tumors collected, fourteen were from the mesoblastic elements, and ten from epiblastic elements. The hyaline masses probably resulted from the degeneration of mesoblastic tissue. The term cylindroma should only be employed as an adjective.

An Astragalus.—Dr. R. H. Sayre presented an astragalus from a case of club foot. The specimen had been removed by operation from a patient, aged twenty-six, with very exaggerared talipes varo-equinus. After extensive incision of the soft parts on the inner side of the foot, he was unable, after reducing the varus, to get rid of the equinus; hence, the astragalus was enucleated. This bone presented a very different appearance from the normal astragalus. Its superior articular surface was not more than one third the usual size; the body of the bone was almost completely absent; the neck was much twisted inward and the surface which should articulate with the scaphoid was much altered. The astragalus was bent downward on itself at a very sharp angle. The larger part of it was entirely free from articulation with the bones of the leg. After removing it, it was found that the os calcis was bent inward at an angle of about 45°, so that it was necessary to remove a **V** shaped section from the outside of the os calcis in order to efface this curve. In these old club-feet it was usual to find more or less distortion of the bones. This was about the first astragalus that he had felt compelled to remove in an adult in order to reduce the deformity, but the great alteration in the bone seemed to fully justify this procedure. No more convincing proof could be given of the importance of overcoming the deformity in club foot while the bones were still flexible.

Abscess of the Liver.—Dr. J. S. Thacher presented specimens from a case of abscess of the liver. The man was operated upon six years ago, in Egypt, for abscess of the liver following an attack of diarrhœa. After wearing a drainage-tube for ten months, he recovered completely, and according to his statement, remained well for five years. He entered the hospital last fall complaining of diarrhœa and some abdominal pain. There were a few streaks of blood in the fæces, and he had also the symptoms and urinary signs of nephritis. The liver showed a distinct enlargement and increased hardness. He left the hospital after a few weeks, and did not return until ten days ago. When readmitted, the left lobe of the liver was found extremely prominent—a large, irregular mass projecting in the epigastrium. The right lobe of the liver was less prominent and softer, but was not easily palpated on account of ascites. He had been twice tapped for ascites. He was tapped again in the hospital, and the fluid on examination showed a few

"budding cells." At the autopsy it was found that the part of the liver which had formed the tumor was not that which was most diseased; it was waxy, degenerated, and hypertrophied. The right lobe of the liver was deeply excavated by an enormous abscess. The spleen and kidneys also showed waxy degeneration. The fact that he had been operated upon before for abscess of the liver, and that there had been no elevation of temperature in spite of the large abscess, were the most interesting features.

Cerebro-spinal Meningitis.—Dr. F. Ferguson presented the brain from a case of cerebro-spinal meningitis. It was removed from a man, thirty four years of age, who was admitted to the New York Hospital on February 5, 1894. He was found unconscious in the street, and was brought to the hospital in an ambulance. On admission he was so extremely drowsy that it was impossible to get from him a satisfactory history. He stated that for two past weeks he had suffered from headache and general pains, and that the illness began with chills, vomiting, fever, and cough. He also seemed to have some pain in his chest. The expectoration was blood stained, and according to his statement had been so for two days. The silghtest touch appeared to cause him the greatest pain. The temperature was 102.4° F.; respirations, 36; and pulse, 92. Physical examination disclosed a soft systolic murmur over the heart apex, but otherwise the thoracic examination was negative His pulse was slow, regular, and of good tension, with corresponding heart action. Examination of liver, spleen, and abdomen was negative. He was anæmic, but well nourished. His urine had a specific gravity of 1.022; it contained no albumin or sugar, and microscopical examination was negative. The pupils were contracted. On the day of admission he had a convulsion at 4 P.M., and at this time eighteen ounces of urine were drawn by catheter. He was restless and noisy all night. The following day he complained of headache. The head was shaved and an ice-cap applied continuously. The attending physician, Dr. G. L. Peabody, made a diagnosis of meningitis He was treated with large doses of sodium iodide. The temperature remained at 102° F., while the pulse varied from 92 to 102, and the respirations from 28 to 40. On February 7th his temperature fell one degree in the morning, but rose in the evening to 104° F., the pulse being 100, and the respirations 32 per minute. He was so noisy and restless that night that morphine was given, and on the following day he was still restless and was tearing the clothing, although unconscious. At 5 P.M. his temperature was 103.8° F.; pulse, 106; respirations, 28, and shortly after eight o'clock he died. At the autopsy both the right and left ventricles were found slightly dilated, and the cardiac muscle was anæmic. The lungs were congested and contained numerous punctate hemorrhages in the most dependent parts. With the exception of the spleen, which was rather large and soft, the thoracic and abdominal organs presented nothing of special interest. On removing the calvarium the dura mater was found congested and firmly adherent to the skull over the left cribriform plate. While the meningitis in this location appeared older, extension upward through the cribriform bone and dura could not be recognized. The pia mater everywhere contained pus and lymph, which, however, were more abundant over the vertex of both hemispheres, and over the posterior surface of the cord in the lumbar region. The fourth ventricle also contained pus. On microscopical examination of the brain the pia mater everywhere was found to be the seat of intense inflammation, with great hyperæmia and numerous punctate hemorrhages. On following the vessels through the cortex they were found to be the seat of innumerable small round cells, some of them apparently in the walls of the vessels, and some in the perivascular spaces. Adjacent to the dura the cortex of the brain in places was infiltrated with an unusual number of small round cells, especially at the base of the left frontal lobe, where, over an area of nearly two centimetres in diameter, the entire cortex of the brain was infiltrated with pus. Over this area the dura mater was also extensively involved. Collections of small round cells were also found in limited areas along its external surface. Examination of the cribriform plate and the ethmoidal sinuses failed to show any lesion beyond intense hyperæmia. Bacteriological examination of sections revealed numerous diplococci, identical with the *micrococcus pneumoniæ crouposæ*. The speaker exhibited culture tubes showing the characteristic development of these organisms, and also microscopical slides. He stated that pure cultures of these organisms had been taken from several parts of the brain and spinal cord. In the vast majority of cases of cerebro-spinal meningitis examined by him during the past three years this micro-organism had been found.

Acetabular Form of Hip disease.—Dr. V. P. Gibney presented a specimen illustration. It was taken from a boy who was eight years of age at the time he was first admitted to the hospital, on January 9, 1889. He had already been treated for hip-disease three years, and had worn a protection splint for one year. On admission there was an immense abscess on the outer aspect of the thigh. The inguinal glands were much enlarged. There was a range of motion over 35° or 40°. Two days later the abscess was incised under ether, and on January 26th another sac was incised. In June, of 1890, the sinuses, three in number, were still discharging. They were curetted under cocaine, and this was repeated on January 6, 1891. He was discharged from the hospital shortly afterward. At this time the sinuses were discharging very slightly, the limb was in good position, and he was still wearing a brace. On January 29th of the same year he was readmitted with the sinuses discharging very freely. Shortly after this an abscess was opened, and from this time until October the sinuses were curetted several times. During the month of October he was etherized, and the sinuses on the inner and upper third of the thigh were found to communicate with a sinus in the inguinal region above Poupart's ligament. Tents were drawn through and through. There was no question then about the acetabulum being perforated. Up to April, 1893, these sinuses had variable discharges, and were occasionally curetted. The boy spent that summer in the country, and on his return in the fall the discharge from the sinuses was very slight Early in December, 1893, one sinus remaining above Poupart's ligament was curetted, and the ilium found necrotic. A large drainage tube was inserted. The sinus was scraped thoroughly and a shell of bone removed. The operation was followed by high fever and much pain, and a few days later an abscess formed at the back of the ilium. The boy died of tubercular pneumonia, and the autopsy was made by Dr. H. S. Stearns, on January 24, 1894. The base of the left lung was found to be full of tubercular nodules the size of a pea. The apex was œdematous, the remaining portion consolidated. The whole lower half showed a fairly intense pleurisy with a fibrinous deposit and two ounces of pus. The left lung showed a few recent adhesions behind a large tubercular cavity in the lower part of the lung, with trabeculæ running through and through, and also three or four tubercular deposits at the apex just undergoing softening. The kidneys were slightly enlarged, nodular on the surface, with non-adherent capsules, and markings distinct. The stomach and intestine were normal. The spleen was decidedly enlarged, and contained nodular tubercles. The liver was very much enlarged, weighing four and three quarter pounds, and was lardaceous. The peritoneal cavity contained three or four ounces of pus. The specimen itself showed no disease in the head, neck, or shaft. At the time of section the trochanter itself presented a normal appearance, but the acetabulum was broken down throughout the upper portion, and there was a large hole into the pelvis.

Dengue.—An epidemic of dengue is raging in Jeddah among the pilgrims recently returned from Mecca.

(From our Special Correspondent.)

COLLEGE POLITICS—COMING ELECTION AT COLLEGE OF SURGEONS—RIGHTS AND ASPIRATIONS OF FELLOWS—WANT OF RIGHTS OF MEMBERS—PROPOSED NEW CHARTER—DEFENCE OF MR. ANDERSON'S CASE—LAWRIE, OF HYDERABAD IN ENGLAND—SPECIAL MEETING TO HEAR HIM—QUAIN'S DICTIONARY—SPREAD OF SMALL-POX.

LONDON, June 23, 1894.

"COLLEGE POLITICS," as affairs connected with the Royal College of Surgeons are commonly called, are just now to the fore. By the way, I do not know why one particular college should thus be spoken of, unless that the members are so numerous that the fellows may fancy that the concerns of their smaller number interest the latter. They do, indeed, but in a different sense. The fellows have the election of the council and desire further rights. An election is just at hand for three seats on the council, and there are five candidates. This is the reason college matters are the subject of the week. The members have no voice in this or any other college affair, and therefore are only interested in candidates on personal grounds. Although many questions arise, and there is some expectation of a new charter being applied for, it must be confessed that the interest evinced in the election is rather languid. One candidate, supported by the association of fellows, actually neglected to send in his papers in due time and is therefore ineligible. Another claims support because he lives in a provincial city. Another as the senior fellow. Another is supported by the new society of fellows, which has no programme and apparently no *raison d'être*. When the few hundred fellows admit the members to their rights, every college matter will interest the whole profession. Then a new charter may be of some value. Anent the present position, the association of fellows has passed a resolution that "such changes as the body of fellows may desire should be embodied in a new charter." Not a word about what members may desire.

Before leaving the college I may mention that the council at the last meeting appointed two of their number to represent the college on a committee that has been formed to carry the case of Mr. Anderson before the Judicial Committee of the Privy Council. Important civil rights are involved, and Mr. Anderson has been fighting the cause of the profession as well as defending himself.

Surgeon Lieutenant-Colonel Lawrie has come from Hyderabad to still further demonstrate the results of the Chloroform Commission, which is due to his labors. He has already appeared at one or two of our hospitals and been received with the cordiality his work deserves. Further, it has been arranged to hold an extra meeting of the Royal Medical and Chirurgical Society on July 3d for the express purpose of hearing Dr. Lawrie, who will endeavor to show that chloroform has no effect upon the heart, and that it is useless to watch the pulse during the administration of the anæsthetic. Lawrie's views are, of course, well known, but it will be very interesting to hear them from a man of such striking personality, besides which we may expect an adequate discussion when our premier society holds an extra meeting after the conclusion of the session for the purpose of hearing Surgeon Lieutenant-Colonel Lawrie.

A second edition of "Quain's Dictionary of Medicine" was issued on Monday. This valuable work of reference—which is so well known—first appeared nearly twelve years ago and speedily achieved success. Many changes have taken place in these twelve years. The death of some of the contributors has necessitated their share of the work being entrusted to others. A number of new articles are also inserted, among which I may instance Greenfield, on Microbes; Sidney Martin, on Immunity and Phagocytosis; and P. Manson, on Negro Lethargy. The last named has also revised his article on Filaria Sanguinis Hominis. The rapid progress of knowledge and the changing way of regarding some facts has in fact rendered revision necessary on the part of most of the writers of the first edition, and their authority is perhaps a sufficient guarantee that they have done this work carefully. I note, however, that the venerable editor declares himself still "personally responsible for the work, of which no portion has been issued without being carefully revised by him." Really, therefore, Sir R. Quain may claim to be a very industrious editor, for many of the articles are by the foremost authorities, and can receive no additional importance from any reviser, and the reading of the two volumes, in which the work now appears, comprising 2,500 pages, is a task which few aged physicians would care to undertake.

The spread of small-pox continues to create anxiety on the part of sanitary authorities. A number of provincial towns have suffered, and in not a few cases the disease has been brought by tramps, and where vaccination has been neglected the consequences have been such as were anticipated by medical men.

RELIABILITY OF STATISTICS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Carl Beck, in his letter in the MEDICAL RECORD of July 21st, has very cleverly ignored everything charged against him, except the date of the recovery of the child reported as Case IX. In this matter he convicts himself of inaccuracy, for the dates he gives do not not agree with each other, or with the time mentioned in his published history of the case. The history I gave for Dr. Beck's information was obtained from the mother, who nursed her child through a serious illness, and must be presumed to know the time of recovery with more certainty than the father. Indeed, even the medical attendants seem to have obtained their revised history from her. In proof of this, and to show how little the father remembered of the particulars, I may quote from a clipping of a letter from Dr. Voegtle, dated June 28 and 30, 1894, which Dr. Beck sent me in explanation of his inability to give me a few facts about this case. Dr. Voegtle writes, evidently in answer to a request of Dr. Beck to obtain these facts: "Will attend to it in the next few days; was there, the wife is in the country, and the husband himself knows nothing definitely about it."

As to the relative merits of exsection and incision, of what value is Case IX. when I have proved it to be one of resection following an exsection?

Again, what value can be ascribed to Dr. Beck's statistics on exsection when they are based on cases, among which, as I have shown, are some in which no exsection was performed? Therefore I repeat: Statistics in order to be valuable should be, as to their material facts, correct.

ARNOT SPENCE, M.D.

July 27, 1894.

TRANSPORTATION OF THE INSANE TO HOSPITALS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of July 21st, page 76, in regard to the "Transportation of the Insane to Hospitals," you say, "those in charge of our public hospitals have absolutely nothing to do with the manner in which patients are brought to them." You are mistaken so far as New York State is concerned. It is the practice for the Superintendent of the Poor of the County to notify the asylum authorities, and they send attendants to take the lunatic to the asylum. It is very exceptional in this county for private persons to take lunatics to the hospital. I think the rules of the Lunacy Commissioners require the insane to be taken by their own attendants on notice to the hospital authorities.

A. D. KENNEDY.

MORRISVILLE, N. Y., July 23, 1894.

Medical Items.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 28, 1894.

	Cases.	Deaths.
Tuberculosis	92	112
Typhoid fever	21	12
Scarlet fever	38	4
Cerebro-spinal meningitis	1	3
Measles	42	5
Diphtheria	163	38
Small-pox	3	0

A Varied Diet.—An inquest was held in London, not long ago, on the body of a man who had died suddenly. The man used to make his living by going about to the different "pubs" in the evening, and eating anything that was offered him, for a small monetary consideration. He died after an operation for intestinal obstruction, and at the autopsy the following articles were found lodged in various portions of the digestive tube: A bullet, twenty or thirty pieces of cork, twenty pieces of tinfoil, a piece of string eighteen inches long, with corks attached, and a piece of leather nine inches long, with a hook at each end.

In Memoriam.—Dr. Samuel T. Hubbard, the last survivor of the original members of the New York Society for the Relief of Widows and Orphans of Medical Men.

At a meeting of the Board of Managers of the New York Society for the Relief of Widows and Orphans of Medical Men, the following remarks were read by Dr. Andrew F. Currier. On motion of Dr. Charles A. Leale they were ordered entered on the minutes of the Board. It was also ordered that a sufficient number of copies be printed and sent to Dr. Hubbard's family, to the medical journals of the city for publication, and to the members of the Society. It was also ordered that they be incorporated in the annual report of the Society: "Died, June 1, 1894, Dr. Samuel T. Hubbard, at the age of eighty six. This is the last link which bound us to the founders of this Society. Of the original members whose names appear on the list for 1842, all are gone now; the last leaf has fallen from the tree. The fathers are no longer with us, they are but a memory, a reminiscence. 'The king is dead, long live the king!' Dr. Hubbard was our Nestor, and I do not see how one could have been very long in his presence without being strongly attracted by his most lovable personality. It was not the attraction of a weak old age, it was not the attraction of an overpowering intellectuality. No, his was the vigor of the rugged oak which is in its prime when other trees around it are decaying, or of the stanch old ship with timbers sound and spars unbending after many a storm, being made of honest material through and through. He made you think of Moses, with his more than fourscore years, looking over into the promised land, his eye undimmed and his natural force unabated, and from the heights of his serene old age I doubt if one ever saw him looking back to the remote days of the past, and making comparisons unfavorable to the present. It would not have been like him to do so, for his life, so far as I have known it or could ascertain, was one of charity and beauty. There is something about the physicians and surgeons of New York of half a century ago, a subtle quality, which it seems to me is not developed to the same degree with us. I do not mean genius, though Mott and Parker and Kearney Rodgers and others of our early *confrères* possessed that. It may be that it was strong common sense, or something allied to it, a power of handling men and women to advantage, a *savoir-faire*, and, perhaps, in our more assiduous cultivation of science we have somewhat overlooked that important qualification. Such a quality our dear friend possessed to a considerable degree. In the meetings of our Society how we shall miss him. He was always present, always prompt in his attendance, genial and wise in discussion, leaning toward the broadest charity in the objects for which our Society is conducted. Peace to his ashes! His memory will long be fragrant among us.

"'His life was gentle, and the elements so mixed in him, that nature might stand up and say to all the world, This was a man!'"

A Centenarian.—A woman is now living in a Home for the Aged in Sables d'Olonne, France, who was born in 1790, being, therefore, one hundred and four years of age. She is in full possession of all her faculties and receives daily a number of visitors, who are attracted by the reports of her extreme age, entertaining them with her lively conversation and witty repartee.

The Bicycle for Women.—The bicycle has become the fashion even for women, and the following wise advice should prove of interest to physicians. Dr. Laura Liebhardt, in discussing before the Colorado State Medical Society the question of bicycle exercise for women, declared that "the majority ride with the saddle too low," and that this is responsible for cramping of the chest, straining the back, and impeding full action of the muscles of the leg. There results a constant tension of the muscles above the knee, which gives a short, awkward stroke, as the reach is too short. The seat should be amply high for the entire leg to be extended and give to these muscles a second of relaxation on the downward stroke of the pedal. The knee must have perfect freedom, and in this respect a woman finds herself particularly handicapped, as she is unable to make the entire stroke with the action of the knee limited by a dress skirt. In Paris they do not stop with the unsightly bloomers, but have almost universally adopted the practical, yet far too radical, knickerbockers. This striking costume attracts but a passing notice, for the *rationale* of it all appeals to the French mind; but as we have fortunately not yet reached the Parisian standard, it is to be hoped that knickerbockers will confine themselves to spins in the mountains. Wheelwomen also subject themselves to needless jars by jumping instead of gliding from the wheel. They should be taught to mount and dismount from either side as men are wont to do. Corsets on the wheel, as elsewhere, should be denounced in the strongest terms, although nearly one half of all wheelwomen tie up their muscles in this barbaric fashion. Many condemn cycling on the ground that the movements are identical with those called forth in running a sewing-machine. Machine-running stimulates more the faulty way of wheeling, and the position is almost identical with that assumed when the handle-bars and saddle are placed too low. In wheeling there are a greater variety of movements and less tension. Two-thirds of all women who ride wheels foolishly incur great risks by riding during certain periods, even to the extent of hill climbing, when they should never mount a wheel, except for short distances, during the first two days. During the discussion the general opinion seemed to be that the saddles in use were hardly proper. The long, wide saddle suspended between springs was considered very much superior to the rigid or hard models. A saddle much wider throughout was considered desirable, and cases were quoted to substantiate this claim.

Signs of Death.—A correspondent of *The Lancet* writes that he was called to see an old lady who was believed to be dead, but whose appearance was so lifelike that the family dared not bury her until they were absolutely certain that death had actually occurred. To quiet their apprehensions the physician applied a series of tests with more or less confusing results. The following were the tests in the order in which they were applied: 1, Heart-sounds and pulse—absent; 2, respiration

—absent; 3, temperature of the body 60° F., the same as that of the atmosphere of the room; 4, a needle left for some time in the substance of biceps muscle showed no signs of oxidation; 5, electricity—no response to electrical stimulation of the muscles; 6, a ligature tied about the arm caused no swelling of the veins below; 7, upon opening a vein the blood was found to be fluid; 8, the subcutaneous injection of ammonia gave rise to a dirty-brown stain, said to be indicative of commencing decomposition of the tissues; 9, cautious movements of the joints revealed a slight stiffness of rigor mortis; 10, upon holding the hand up against a powerful light, the red line of light between the fingers was as distinct as in the case of a living person; 11, the temperature of the room was raised, and when evident decomposition had set in the woman was pronounced dead.

Hyperpyrexia.—Dr. Richet reports a case of intermittent fever in a woman in which the temperature rose one day from 102° in the morning to 113° F. in the evening. On two other occasions the fever rose to 115°. Under the influence of quinine the temperature fell to 97°, but rose again to 115° F., when the remedy was discontinued. The patient finally recovered.

Explosive Compounds.—A Parisian lecturer in speaking of the dangers of polypharmacy enumerated explosion as one of them. He had collected several formulæ of this anarchistic quality, among them being a liniment of tincture of iodine and turpentine, another a mixture of chromic acid and glycerine, and a third a tooth-powder composed of pulverized charcoal, cinchona bark, and chlorate of potassium.

Diseases of the Rectum.—Our esteemed friend, Dr. Baudoin, of the *Progrès Médical*, takes an interest, and a very intelligent one, in medical matters in this country. He is doing a good work in correcting some errors and misapprehensions concerning America which our French *confrères* entertain, and deserves our gratitude therefor. Some of our customs, however, strike him, not unreasonably, as peculiar, if not amusing. Among these is the multiplication of specialties, in which he thinks we have gone ahead even of our English cousins. The specialty of rectal diseases is one that recently engaged his attention, and he has very kindly attempted to provide its professors with a name. He thinks they might be called rectists, after the analogy of oculist and aurist, or better perhaps, because longer and more sonorous, proctologists. The *Quarterly Journal of Proctology* would be an excellent name for our esteemed contemporary by the Falls of the Ohio.

The New French Medical Law.—The new law regulating the practice of medicine in France came into force on December 1st. As inquiries are frequently made as to the conditions under which foreign doctors may practise their profession in France, the following explanation of their position under the new law may be of interest. We give it on the authority, and almost in the words, of the *Journal des Connaissances Médicales*, the editor of which is Professor Cornil, a member of the French Senate, who was president of the committee which drafted the law, and who, in fact, may almost be described as its author. The new law has taken away the power formerly possessed by the Government of authorizing medical men having foreign diplomas to practise in France. Under the new law no one is allowed to practise unless he possesses a French diploma of doctor of medicine. Certain facilities may, however, be granted, according to the circumstances of the case, to foreign doctors wishing to obtain a French diploma. What these are may be gathered from a circular letter which the Minister of Public Instruction has lately addressed to the rectors of the medical faculties throughout France. The periodical registrations required of French medical students may be partly or totally dispensed with, but exemption from examination can never be more than partial. In no case shall candidates be exempt from examination in more than three subjects. Such exemption as may be allowed will be granted by the minister on the advice of the faculty of medicine before which the candidate wishes to present himself, and of the Consultative Committee of Public Education. In considering applications the faculties must concern themselves solely with the value of the diplomas and scientific works submitted to them by candidates. The provisions apply to French citizens who have obtained a medical qualification in some other country as well as to foreigners, and, indeed, the Minister instructs the medical faculties to exercise special care in weighing the claims of Frenchmen who, on the strength of a foreign diploma, ask for exemption from part of the tests which are compulsory in the case of their countrymen who go through the ordinary course at home. The course to be pursued by an English medical man who wishes to practise his profession in France is, therefore, to select one of the recognized faculties—Paris, Montpelier, Nancy, Lyons, Bordeaux, Lille, or Toulouse—and submit to it his papers with whatever records of scientific work or other claims to professional recognition he may possess. He will then be informed in due course what examinations he must pass before he is pronounced *dignus entrare in nostro docto corpore.*—*The British Medical Journal.*

A Swiss Paper relates that of the seven thousand physicians who attended the Medical Congress in Rome, only five hundred were invited to the garden party in the grounds of the Quirinal, while there were present about two thousand other persons, many of whom had found a way to buy tickets at $10 each.

Phosphorus Butter.—Comby (*Prat. des Mal. des Enf.*, 1893) recommends the following prescription, a modification of Trousseau's, for the preparation of iodo phosphorated butter, which may be used as a substitute for cod liver oil in hot weather:

℞. Fresh butter	1 lb. 1½ oz.
Iodide of potassium	gr. iv.
Bromide of potassium	gr. xv.
Chloride of sodium	ʒ ij.
Phosphorus	gr. ¼.

About one-third of an ounce daily, spread on bread.

Greek Typewriting.—A lady in Cambridge announces in the London medical journals that she is prepared to typewrite Greek manuscripts. She will have plenty to do when this is adopted as the official language of international congresses.

Insanity from Tea drinking.—In a report upon insanity in Ireland, recently issued, attention is called to the immoderate use of tea as a cause of mental disease among the poorer classes. "While the moderate use of properly prepared tea," the report states, "is regarded as innocuous, or even beneficial, in its action on the nervous system, its ill effects, when decocted or over-infused, on persons who make it their staple article of dietary, are dwelt on by almost all the resident medical superintendents in their several reports. Undoubtedly, the method of preparation adopted, and the excessive use of this article of diet, now so general among our poorer population, tends to the production of dyspepsia, which in its turn leads to states of mental depression highly favorable to the production of various forms of neurotic disturbance." The tea used is generally of an inferior quality, and the method of preparation is to put a quantity in the teapot early in the morning, and to allow it to stew during the day, water being added as required. The excessive use of tobacco, also, especially among the young, is thought to contribute in a minor degree to swell the statistics of mental failure.

A New Lip.—Dr. Berger has presented to the Paris Academy of Medicine a young woman whose under lip was restored by a graft taken from the arm. The new lip presented a very natural appearance, the vermilion border being almost perfect.

CASES IN GENITO-URINARY SURGERY.[1]

I. EXCISION OF THE BLADDER FOR EPITHELIOMA. II. EXCISION OF TUBERCULAR SEMINAL VESICLES, TESTES, AND SPERMATIC CORDS. III. IMPLANTATION OF AN ARTIFICIAL TESTIS AFTER CASTRATION. IV. VESICAL PAPILLOMA OF UNUSUAL DURATION.

BY ROBERT F. WEIR, M.D.,

PROFESSOR OF SURGERY, COLUMBIA COLLEGE; SURGEON TO THE NEW YORK HOSPITAL, ETC.

BEFORE presenting to you the cases of excision of the bladder, a few prefatory words on the subject may, I trust, be allowed.

Tumors of the bladder of a malignant character are encountered in about eighty per cent. of neoplasms of this organ. Tumors of any kind are very rarely situated at the summit or on the anterior face of the bladder or in the trigone; but the region between the summit and the mouths of the ureter, and especially on the posterior wall, is the usual site of such growths. One-half of the cases of carcinoma, however, invade one or both of the ureteral orifices. Secondary growths occur quite late in the disease, though adjacent gland infection is not uncommon; but the latter are usually situated within surgical reach. The mortality involving the removal of a carcinomatous growth of the bladder reaches, according to Alberran, to nearly fifty per cent. The usual method for removing vesical tumors has been, until quite recently, that of exposing the growth by suprapubic section of the bladder, with its subsequent removal by the knife or scissors, the surgical interference seldom going beyond the mucous or muscular layers at the base of the growth. Recurrence after this method of operation amounts to fifty-seven per cent. The method of a more heroic operation was inaugurated first by Sonnenberg, in 1884, who then extirpated nearly the entire bladder, except the neck, trigone, and ureteral orifices. The patient survived five weeks. At the autopsy a new but comparatively small bladder, formed of the remnant of that organ, and a modified cicatricial tissue was found. A further step in advance, however, was made in 1885, by Antal, who evolved a procedure which has proved since of great importance in connection with the surgery of this region of the body. It consisted in the demonstration that the peritoneum could be peeled off from the summit and posterior wall of the bladder without very much difficulty. Since that time a number of cases, nearly twenty in number, of resection of more or less considerable portions of the bladder walls outside of the limits of malignant growths have been undertaken. The benefit that accrues from this wider removal of a malignant growth is seen at once in the diminished chances of recurrence after such operations. From fifty-seven per cent., as already quoted as the proportion of recurrences after the ordinary removal, it has been diminished by this latter procedure to twenty-eight per cent. With the encouragement afforded by this improvement in the technique of the operation, surgeons have been led to undertake the removal of larger and larger portions of the bladder, and even total ablation of this organ has been successfully undertaken. Bardenheur, in 1887, removed the whole bladder in a man, aged fifty seven, for cancer of the base that involved the ureters. This was easily accomplished, the peritoneum peeled off readily, though considerable hemorrhage was encountered as the neck of the bladder was divided. This was readily checked by tamponing the parts. Death, however, resulted on the fourteenth day from uræmia. Two other extensive resections, though not total ones, have since been reported by the same surgeon, one of which has remained completely cured up to the date of the last report, and one died five months later from a recurrence of the disease.

The difficulty connected with such extreme operations, aside from the immediate results of shock, etc., was centred in the disposition of the severed ureters. Bardenheur, in his experiments on animals, endeavored to solve the difficulties by implanting them into the rectum, but in all the animals experimented upon death resulted either from dilatation of the ureters, due to the contraction at the place of implantation, or a fatal issue ensued in consequence of infectious pyonephrosis of rectal origin. Tuffier, the French experimenter, also had the same result. Similar fatal results have occurred in the human subject in nearly every instance where this implantation into the rectum has been resorted to.[1] In women, where extirpation of the entire bladder has been twice resorted to, the vagina has been used as a retentive sac for the urine with some satisfaction; but in the male two other methods have been suggested that are more worthy of trial. Le Dentu, having accidentally wounded the ureter in a gynecological operation, brought its kidney end to the abdominal wall, where it was fastened by sutures. The patient died on the thirteenth day. No urethral or kidney changes were found. Pozzi had the same accident in an operation and resorted to the same expedient. The patient recovered and urinated through the abdominal wall for three months, when the discomfort of this discharge demanded a nephrectomy, which was performed. The ureter and kidney showed no abnormal changes.

While it is probable that in accidents of this nature, occurring in the future, such methods of diverting the urinary discharge will be but seldom resorted to, since the union of a divided ureter has now been satisfactorily proven to be capable of being accomplished by the methods of Van Hook and Kuster, yet the results of the abdominal attachment of the ureteral end have, in the main, been encouraging. A better method than this, however, exists. De Paoli and Brusachi have shown us, by experimentation on animals particularly, that if a small portion of the bladder should be left, let us say after extirpation of a tumor involving the ureteral orifices, the ureters can be inserted into the portion of the remaining bladder-walls, without subsequent contraction, by first making an opening through the thickness of the bladder, cutting away around this opening a small circle of the mucous membrane, and then pushing through the opening in the bladder wall the end of the ureter, having enlarged the orifice of this by splitting it up a short distance, as is usually done in the urethra in amputation of the penis, and then stitching the ureteral mucous membrane to the mucous membrane of the bladder. External to the bladder-wall this fixation is reinforced by other sutures. This method is warmly indorsed by Guyon and Alberran, and has been successfully resorted to in the human sub-

[1] Read at a meeting of the Practitioners' Society, held 1894.

[1] Chaput: Centrabl. f. Chirurg., No. 14, 1804, reports a case of implantation of divided ureter into colon, with, five months later, no evidences of renal infection.

ject by Penrose, of Philadelphia.[1] Kummel, still bolder, after removing the entire bladder in a woman, attached the ureteral orifice to the vesical end of the urethra. His patient, however, did not survive long enough to test the value of this procedure. Novaro,[2] McArthur,[3] and Baum have also implanted ureters into the bladder to relieve utero-vaginal fistulas.

Another method has been suggested which is not so attractive. It is based upon the fact that a ligature of the ureter determines usually atrophy of the corresponding kidney. It has, therefore, been suggested that in an extirpation of the bladder involving the ureteral orifice the divided ureter be treated in this fashion.

This brief account of the methods of undertaking an operation of this extent would hardly be complete without a slight reference to the advantage claimed for the enlargement of the operative field by symphyseotomy. This section will permit of a separation of from six to eight centimetres (two to three inches) and thereby the lower portion of the bladder will be literally exposed. From experiments upon the cadaver, as well as my experience on the living subject which is to be presently related, I am convinced that this latter addition to vesical surgical procedures will rarely be needed. The bladder can be removed, or rather that portion of it usually involved in a neoplasm can be widely removed, without much surgical difficulty, by the simpler measures of peeling off the peritoneum, not only from its summit and posterior walls, but from its lateral surface, aided by the employment of the position of Trendelenburg.

My first experience in the removal of a considerable portion of the bladder, and the ease with which the peritoneum can be lifted from that organ, occurred in 1891, when a man, fifty-nine years of age, was admitted, in the month of December, to my wards in the New York Hospital, with a history that eighteen months previously blood had appeared in his urine, which after an interval of several months recurred and persisted up to the date of his entrance into the hospital. He had but slight pain in the bladder, with moderately frequent urination. The urine was more or less persistently bloody, without evidence of renal disease or sugar. No stone was found in the bladder by sounding; the prostate was normal in size; bimanual examination gave negative results. A cystoscopic examination, under an anæsthetic, revealed two tumors on the posterior wall, the right one a little larger than the other. On December 26th, with a Petersen bag in the rectum, into which was injected six ounces of water, and with seven ounces of Thiersch's solution injected into the bladder, the patient placed in Trendelenburg's position, by a three-inch incision in the median line the bladder was exposed, the preperitoneal fat "clawed" up from the pubes toward the umbilicus, and the bladder then opened by a vertical incision. The lips of this incision were held apart by silk ligatures. A single tumor, the size of the distal phalanx of the thumb, was found on the upper part of the posterior wall, somewhat to the right of the median line. To effectually get beyond the growth the peritoneum was stripped off from the summit and the posterior surface for a space reaching from one seminal vesicle to the other and down nearly to the prostate. In so doing, at one point a rent was made in this membrane, but this was promptly sewn up with silk sutures and gave rise to no further inconvenience. A triangular portion, including the tumor, but going widely from its base, about two and a half inches on each of its sides, was finally removed from the posterior wall of the bladder. As I found considerable difficulty in closing by sutures the lower angle of the space thus formed in the bladder-wall, I abandoned the attempt to close any portion of the bladder, believing this to be safer for the patient. Iodoform gauze was therefore packed between the bladder and the peritoneum, the bladder itself filled with iodoform gauze around a rubber catheter passed to the bottom of the organ and the drainage accomplished in this way, and by ordinary antiseptic dressings applied over the wound in the abdominal wall. The patient did well, his wound very nearly closed; but on February 19th he was attacked by erysipelas and died four days later, seven weeks after the operation. At the autopsy it was seen that the suprapubic wound had very nearly healed, the gap in the bladder on its posterior wall had closed over by a smooth cicatricial surface, and everything promised well if life had continued longer. This line of excision of the bladder-wall is well shown in Fig. 1, which accompanies this.

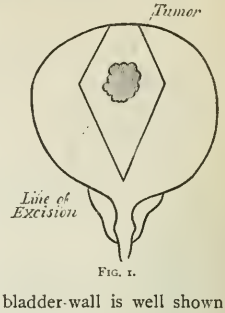

Fig. 1.

I. Excision of the Bladder for Epithelioma. Case I. *Epithelioma of the Bladder; External Resection of the Bladder-walls.*—A man, aged fifty-five, entered the New York Hospital, February 25, 1893, with the history that in August, 1891, he began to pass blood with his urine. This persisted with every act of micturition for several months, when it stopped for four months and then recurred. Other hemorrhages at much less intervals took place, until April, 1892, when a suprapubic cystotomy was done by Dr. Park, of Buffalo, and two tumors removed from the bladder, one the size of a walnut, and the other no larger than a bean. A fistula continued for a considerable time, but was healed at the end of fourteen weeks.

In September, 1892, another hemorrhage occurred, and since that time blood has at irregular intervals appeared in the urine. On examination there was found in the abdominal wall, just above the symphysis, in the cicatrices of the previous operation and at its upper part, a tumor the size of an English walnut, elevated above the surrounding skin and reddened on its surface with an indurated area surrounding its base about two inches in diameter. A cystoscopic examination, made by Dr. William K. Otis, revealed a tumor on the postero superior wall of the bladder. There were some enlarged glands of a superficial character in each groin.

On March 1st, under ether, with a rectal distention by a double Barnes bag containing eight ounces of water,

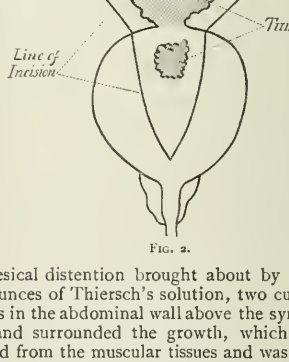

Fig. 2.

and a vesical distention brought about by the injection of six ounces of Thiersch's solution, two curved vertical incisions in the abdominal wall above the symphysis were made, and surrounded the growth, which was readily separated from the muscular tissues and was found eventually to be attached to the summit of the bladder. The peritoneum was then pealed off by a blunt dissector, aided by light cuts from a scissors, from the posterior wall of the bladder down to the prostate, and on each side as far as the seminal vesicles. This whole exposed portion of the bladder was excised, including a papillomatous growth

[3] Trans. Ill. Med. Soc., 1889.

in its centre as large as a walnut, as well as the growth rising out from the summit of the bladder (see Fig. 2). The section of the bladder-walls passed at least from one-half to three quarters of an inch beyond the growths in all directions. The bladder was sewn without difficulty from the bottom with interrupted catgut sutures, which were purposely passed through all its coats; and in one or two places on its summit with silk-worm gut introduced only through its muscular coat for additional support. A small opening was left toward the pubis, through which was passed a Guyon double rubber-tube drain. The wound in the abdominal wall was packed with iodoform gauze and its upper end united by silk-worm-gut sutures. Sterilized dressings were applied. The patient did well after the operation, leaving the hospital eight weeks later all healed, holding his water from three to four hours. The capacity of the bladder was from four to five ounces. About two weeks after the just-described operation of exsection of the bladder, the glands in each groin were also extirpated. A microscopic examination in each of these two cases of resection of the bladder showed the neoplasms to be epitheliomatous in character.

II. Double Castration and Complete Extirpation of the Vesiculæ Seminales and Vasa Deferentia for Tuberculosis.—Germane to the foregoing subject of excision of the bladder is the experience obtained in extirpating the seminal vesicles. Every surgeon has been at times disappointed, in practising the operation of castration on one or both sides of the testes affected beyond salvation by tubercular invasion, at his inability to divide the vas deferens at a height satisfactorily beyond the reach of the disease, even when this is apparently of testicular origin, and is too often compelled to leave the stump of a diseased cord in the wound, hoping that, as happens elsewhere, nature's resisting powers may overcome the probable small quantity of tuberculous material left. All the more is this dissatisfaction increased when he finds either that a tubercular knot exists at the same time on the corresponding side of the prostate, or possibly that a similar involvement can be detected in the seminal vesicle of that side. It is only comparatively recently that endeavors have been made with any encouragement to more radically rid the patient of his encroaching disease. Bungner [1] has advised that in castration the vessels of the cord should be separated at the inguinal ring from the vas deferens, duly ligated and severed, and that traction should be then made upon the vas deferens to such a degree that it would tear across oftentimes at a considerable distance beyond the internal ring. This, however, is an uncertain procedure, and while it is not attended with any risk it does not compare in exactness or thoroughness with the methods that have previously been suggested by Roux, of Lausanne, or Villeneuve, of Marseilles. The latter advised that in such cases the incision, for the castration should be extended in the abdominal wall up to and beyond, if necessary, the internal ring, and down to the peritoneum, which could then by the finger be separated from the lateral walls of the bladder, using the cautened vas deferens as a guide until the top of the seminal vesicle was reached, when the vas deferens could be divided and extracted. Roux suggested in these cases, where the prostate or the vesicular seminales were involved, that a semicircular incision should be made parallel to, and anterior to, the anus, and through this the rectum separated from the prostate; and if the seminal vesicle was involved, that at the base of the prostate a transverse incision should there be made in the fascia covering of the seminal vesicles, whereupon this portion of the generative apparatus could then be readily peeled off from the bladder and removed, when the castration, either previously begun or now undertaken, could be completed after the separation and ligation of the vessels, by making traction upon the vas deferens, when it would come out its entire length like an earthworm from its hole without any further risk to the patient. The following case, in which this procedure was resorted to, will illustrate the ease, if not the efficacy, of this manœuvre.

[1] Centralbl. für Chirurg., No. 46, 1893.

Case II. *Tuberculosis of Testicles, Prostate, and Seminal Vesicles.*—Ferdinand R——, aged twenty-eight, was admitted to the New York Hospital, October 19, 1892, with the history that he had had "inflammation of lungs" when a child. When fourteen to sixteen years of age had enlarged cervical glands, which did not suppurate. Four years ago had gonorrhœa for six months; a year later a second attack. Some gleet noticed at times ever since. Six months ago the left testicle was noticed to be swollen to size of an orange. It became very tender and painful. Treatment by cold and rest reduced it one-half, which size persisted. He then suffered great vesical irritability, urinating every few minutes, noticing a few drops of blood at meatus afterward. Two months later right testicle was similarly affected, both testicles remaining the same size for the past three months. Vesical irritability less for two months, micturition every hour. General health good. No tubercular family history.

Admission: Urine yellow, acid, 1.010, trace of albumin, pus, and blood.

Examination.—Epididymis on each side swollen, globus major and minor enlarged, hard mass between them. Each epididymis tender on firm pressure, skin not adherent. Both cords enlarged, right more so. Right seminal vesicles much enlarged, a nodule also felt in right side of prostate. Tubercle bacilli found in urine, but only when pressure per rectum was made in the rectum on the prostate.

The seminal vesicle and prostate were therefore considered the foci of disease, and in the hope that relieving the patient of these the bladder might be spared permanent invasion a radical operation was advised and practised. Under ether an incision was made on right side from lower part of scrotum carried up over inguinal canal. Testicle and cord exposed and separated from spermatic vessels at internal ring. Testicle softened in places and showed several cavities filled with pus. Cord apparently normal. Fascia of external oblique muscle cut through over canal and cord, vessels separated as high up as possible, ligated, and cut. Here peritoneum was accidentally opened about three fourths of an inch. This was closed by suture. This rent was made in an endeavor to separate the peritoneum from the lateral aspect of the bladder, following the course of the vas deferens, as suggested by Villeneuve; but it was not an easy thing to do, and in carrying it out, as said before, the peritoneal cavity was entered. In the left side an incision was made exposing the testicle and cord, which were separated from the vessels well up into the canal, vessels ligated and cut. The testicles, free from the scrotum, but attached to their cords, were left hanging at the internal rings. Roux's operation was then chosen to follow, with patient in lithotomy position *A*. Curved incision starting at one side of anus was carried anteriorly to other side, allowing the anus and rectum to fall back. Incision carried up until prostate and bladder-wall were exposed. Here the dense fascia binding down the vesicles to the bladder was cut through transversely, giving ready access to the ampulla of the vas deferens and the seminal vesicles. Right seminal vesicle found dissected free from bladder and removed, also the affected portion of the prostate, and subsequently the other vesicle. Both cords with testicles and whole length of the vasa deferentia were drawn out in front from the castration wounds in scrotum. Then the fascia of external oblique was sutured with catgut over a gauze drain. Skin closed with catgut, similarly the incision on left side was treated. The perineal wound was packed with iodoform gauze and sutured with two sutures on either side of anus. Wet dressing. Reacted fairly well.

The subsequent history of the patient was in brief that for the first four weeks urination improved and the tubercular bacilli disappeared, but this amelioration was due to the effect of a small fistulous track that resulted

from the wound in the prostate, and which persisted for nearly seven weeks. After its healing the bladder irritation increased, and injections every second day of ten per cent. iodoform in starch or glycerine were resorted to for some time with benefit. He passed then from observation. The scrotal and ante-rectal wounds healed satisfactorily.

III. The Implantation of an Artificial Testis after Castration.—A case little less serious than those foregoing is the attempt made to replace a testicle lost by the operation of castration. A man, thirty-seven years of age, who had had for nearly two years a tubercular involvement of both testes, the right being most seriously affected, was compelled by the advance of his disease to submit to castration. The left testis, being less diseased, was saved by a process of scraping and packing with iodoform gauze.

When before the operation I announced to him that the right testicle was so much damaged that its loss would be likely to ensue, he begged most piteously that I should not remove the entire organ. This request I endeavored of course to comply with, but found it impossible to do so; but at the completion of the castration in the ordinary way I was enabled to relieve his mental anxiety by resorting to an expedient which experience in other directions had led me to believe might be successful here, and that was to implant into the cavity of the scrotum left vacant and surgically clean by the thorough removal of the diseased parts, a ball of celluloid duly disinfected. This, about an inch in diameter, was placed in the former site of the testis, and the skin drawn over and properly sutured. Healing followed promptly and without any difficulty, and the patient has now worn this artificial testicle since May, 1893, with a contented mind and proud yet of his virile powers. I was led to this procedure, from two or three successful attempts to use celluloid in overcoming defects and deformities. Two years before, I had an opportunity of covering a defect of the skull, produced by a compound depressed fracture, by inserting in the space left after the removal of the depressed bone fragments a thin plate of celluloid one and a half inch by an inch in diameter. This has remained *in situ* without any disturbance to the patient since then. The little lad, the subject of this experiment, has been already shown to you, but I beg to present him again for inspection. The idea of using celluloid as a material to replace bone or cartilage defects originated in the Vienna school with an assistant of Billroth by the name of Fraenkel.[1] Since then it has been resorted to a number of times for this particular defect in the skull, and of late for defects elsewhere. It has been applied, for instance, to replace a loss in the tarsal cartilage of the eyelid. It has also been applied to remedy the removal of the edge of the orbit, and thus aid in keeping the eyeball in position. It has been, moreover, used, even immediately after resection of the superior maxilla, in every case with advantage. Very recently I have utilized it in three instances to overcome a deformity of the nose from sunken cartilages, for the purpose introducing a portion of the celluloid suitably shaped to suit the different deformities; placing the support in position either from without through a small incision, or better still, from within the nostril. The suggestion of this way of overcoming a very troublesome nasal deformity was made by Dr. Lewis A. Stimson, who employed for this purpose either gutta-percha or aluminum. In my judgment, however, celluloid is a material much better borne by the tissues than either of the two substances just mentioned.

Following the example set forth in the case just related, I understand that another testis has been artificially supplied, or simulated by a celluloid one, by my friend Dr. Guiteras, in a case shortly to be published, and also by Dr. Hartley in a recent case.

IV. **Vesical Papilloma of Unusual Duration.**—The last case that I shall venture to bring to your notice, in connection with genito urinary surgery, is one of a tumor of the bladder, which, occurring in a man of fifty-two years of age, possesses the points of interest presented briefly as follows:

1. That it had existed for an unusually long time, for the history showed that the bleeding had persisted off and on for a period of thirty-seven years. This is beyond the duration of the longest period mentioned by Guyon or Alberran, which was in two cases respectively thirty and thirty-one years.

2. That the diagnosis was made most satisfactorily in this instance by the employment of Guyon's method, viz., the urination of the patient into three glasses, in the last of which the most and freshest blood was found. Also, as a corroboration, that, after washing out the bladder, a bimanual examination was made, the catheter being left *in situ*, by which manœuvre fresh blood was pressed out in small quantities through the catheter, or else was washed out of the catheter after it was withdrawn.

3. That in this case a cystoscopic examination failed to reveal the existence of the growth. This investigation, I may add, was made at the hands of one who was particularly expert in the use of this instrument.

4. And what is, after all, of the most clinical importance, was that the tumor—a papilloma about one inch and a half in length and one quarter of an inch in diameter, and quite fibrous in character, with fringes on its free ends—was situated just above and to the right side of the meatus internus urinarius. This tumor was detected in a very ready manner after the suprapubic section had been made, by the insertion of a large Ferguson's glass vaginal speculum. This idea had been suggested by Fenwick, of London, who used such a speculum as a sort of caisson, even with the bladder more or less filled with water or urine, in which case the speculum was to be passed to the deeper part of the bladder, the imprisoned water soaked or wiped out, and the bladder thus exposed carefully inspected. I found it better, however, to wipe out the bladder as well as possible, then introduce the speculum and sweep it along the walls of the viscus; and in this instance, before very long was able to recognize the tumor in the situation just described. Through this same speculum, which was about one and a half inch in diameter, I could and did seize the tumor with a forceps and with a curved scissors cut it off, and then with a Paquelin cautery lightly touched its bleeding surface, and finally packed upon the wound, from which the blood did not entirely cease by the light cauterization, a wad of iodoform gauze and hold it there firmly until all hemorrhage was checked. The whole procedure answered so well these various ends that I beg to commend to your notice the serviceability of this method of examination and operation. It commands a ready view of the whole of the bladder in its lower and posterior parts, which parts are most affected by growths. It enables one to readily recognize the mouths of the ureter, and to pass into them, if necessary, instruments for their further exploration, etc.

The bladder in this instance, after removal of the tumor, was sewn snugly together, and the abdominal wound left open. The patient made a prompt recovery, with a very trifling leakage for eight days, and has remained well since.

The tumor was a papilloma with a heavy fibrous stroma.

[1] See Wiener klin. Wochenschrift, No. 25, 1890, No. 16, 1891, and Frey, No. 3, 1893.

The Czar gave the physician who treated him during his attack of pneumonia last winter the sum of $30,000.

A New Hanging Machine is to be put to the practical test soon in Connecticut. It is so constructed that the weight of the condemned criminal stepping on a platform sets in motion the necessary machinery for his suspension. Some people protested against its use on the sentimental ground that the man hanged would be virtually a suicide.

A MODERN IDEA IN SCIENTIFIC MEDICINE.

By JOHN AULDE, M.D.,

PHILADELPHIA, PA.

THE claim has been put forward, and not without show of reason, that the science of medicine lags behind the other sciences, and that in consequence of this backward condition not only is the average length of life less than it should be, but also that there is an augmentation of the total sickness. Admitting that preventable diseases are far too common, and hence, as a matter of course, the national vitality lowered in proportion, it is still doubtful if the charge above quoted is entitled to stand, since the fact is patent that much has been accomplished, even within the past decade, to alleviate human suffering, to control or modify disease, and to prolong life. It would be foreign to the purpose of this article to take account of numerous and substantial advances effected in this direction, since its object is to direct attention to a modern idea in scientific medicine which gives promise of working a revolution in methods of practice; an idea which involves new and important principles concerning our conception of the phenomena of life itself.

This modern idea, however, is not founded upon speculative investigation, for the facts it embodies and the conclusions upon which it rests have long been recognized by intelligent physicians on both sides of the Atlantic. The novelty consists merely in the arrangement of these facts, deductions, and conclusions which necessarily lead up to this new departure in the domain of therapeutics. Indeed, in the light furnished by our knowledge of life, chemistry, experimental physiology, pathology, and clinical observation, the truths here to be recorded point to the pressing need for radical changes in methods of treating disease.

Neither does it fall within the province of this paper to criticise or expatiate upon the more recent plans that have met with the approval of the foremost physicians throughout the country. Suffice it to say that the facts presently to be brought forward were practically inconceivable without the knowledge recently acquired relating to antisepsis.

By way of recapitulation, and as a preliminary to the following remarks, it should be stated that although a period of thirty-five years has elapsed since Professor Virchow, the eminent scientist, published his memorable treatise upon "Cellular Pathology," but little, comparatively speaking, has been accomplished since that time. Professor Virchow studied, and later depicted, the retrograde changes occurring in the microscopic cell from disease; but no one has thought it worth while to study and depict the nutritional changes taking place in the living cell as a result of medication. The consequence is, therefore, that very many remedies are given on a speculative basis. True, a considerable number of the medical profession now claim to practise what is termed "rational" medicine, as contra-distinguished from empirical medicine; but when the question is asked as to the precise influence which remedial agents have upon nerve cells and upon protoplasm, no one can be found competent to answer.

For example, enthusiastic claims have been made for electricity, and we have in the State of New York, at least, the anomalous spectacle of the same agent being used both to kill and to cure. And when it is considered that no systematic, thorough, and complete physiological investigations have been made with a view to determine the effect of this powerful agent upon the microscopic cell, we may well pause before accepting literally the conclusions of its active supporters. This reservation is not pressed by reason of an absence of clinical results, but rather for the reason that exact knowledge is still wanting.

However, this method of study has recently attracted the attention of the medical profession through the reports of Professor Hodge, of Clark University. This ingenious experimenter found, on exposing the nerve-cells of honey-bees and pigeons to the stimulating effects of the electric current, that certain appreciable changes occurred; but when the action was long continued, or the current strength was increased beyond a variable point, no characteristic change took place.

The experimental evidence undertaken with a view to determine the physiological effects of remedial agents upon the human economy points to the fact that the true therapeutic value of a drug is by no means to be measured by the mechanical effects produced, and it is to be regretted that the disposition to study results rather than methods and principles has found favor with the profession, because of the vicious circle of reasoning set up and the unstable foundation it affords. It is this circumscribed medical horizon which has so seriously handicapped the present generation of physicians. In surgery the conditions are different, since the results attending the use of antiseptics naturally developed the principles upon which antisepsis depended, and thus a foundation was firmly established for asepsis, or the treatment of wounds by exclusion of the septic material.

The rational treatment of disease should be based upon a knowledge of the effects which medicinal substances produce upon the functions of the cell; and since the cells in different portions of the human economy have special functions to perform, and therefore vary in their structure, it follows that no one remedy is likely to affect all cells in precisely the same manner. It must be evident, therefore, to the most superficial observer, that the rational treatment of disease should be based upon the therapeutics of the cell; and to be efficient we must consider the effects of drugs which are seen as well as those which are unseen, as there is no doubt in the minds of clinicians that metabolic changes occur which are beyond our power to demonstrate or comprehend.

The remarkably favorable results attending the use of cold baths alone in typhoid fever furnish evidence that the economy, unaided by medicines, can withstand and finally eliminate the poison of this disease, and to the reflective mind it shows that the ability to resist disease depends upon the integrity and function of the cell—cell metabolism. Indeed, in view of the large mortality in this disease treated by the routine method as contrasted with the low percentage of fatalities with the bath treatment, we are almost forced to the conclusion that medication has been responsible for more deaths than recoveries.

Mercury and arsenic may be selected to represent the effect which poisons have upon metabolism (tissue-change). Being foreign substances and distributed over the system through the blood and lymph, the organism is intent upon their elimination because they are protoplasmic poisons. While we may trace the former to the liver principally, and the latter to the pulmonary structures or the skin, where they are finally eliminated, their elimination, when given in medical doses, is always attended by more or less cellular activity beyond the normal—usually spoken of as inflammatory action. Wherever found, they act as protoplasmic poisons, and it is this property which gives them their therapeutic virtues—when properly administered.

Cellular therapy is concerned in promoting stimulation without irritation and subsequent depression, which is accomplished by selection of the proper remedy and regulation of the dose. It should be borne in mind that both substances mentioned are active poisons, and that however administered this peculiarity remains, *i.e.*, the minimal dosage lessens the degree of toxicity, but produces no change in the action, although it modifies the effect.

Now, to illustrate the underlying principle of the modern idea which I wish to develop, suppose a physician desires to relieve some chronic cutaneous ailment; he administers arsenic either because he knows it is "good" for such cases, or for another, apparently better, reason, namely, because he is aware that the drug is largely eliminated by the skin, and that through this process of

elimination cellular activity will be increased. Still, this latter reason is extremely unsatisfactory, since it lacks definiteness, and besides, the claim will be set up that it would be a contradiction of physical laws to assume that protoplasmic poisons will stimulate the action of organic cells whose constituent elements are principally this peculiar substance. It will be asserted that a disordered condition of the cutaneous structure means a debilitated or exhausted state of the protoplasm composing the cells, and that whether we consider the physical or nervous mechanism concerned in promoting their activity, it would be equally unfortunate to expose them to the disturbing and depressing influence of a rank poison.

This process of reasoning, however, can easily be set aside as fallacious, since clinicians well know the stimulating effects of arsenic in all cutaneous affections. The scientific explanation appears to be that as all poisons are irritants, the degree of irritation may be so modified by dosage that the irritation is limited to that of mild stimulation. Thus, the prick of a pin is stimulant, while the stab of a bowie-knife may prove fatal.

The idea of treating diseased conditions of the human organism by the exhibition of medicaments which tend to the restoration of the function of the cells in the part affected is a very seductive one, but its practical adaptation is attended with difficulty. The obstacles in the way of its tentative employment in many diseases, however, are not insuperable, owing to our knowledge concerning the physiological action of drugs. Thus, a drug which is eliminated through the skin, kidneys, liver, or pulmonary apparatus, will usually increase the functional activity of those structures, necessarily through augmentation of cellular activity. But there is a limit to stimulation thus produced, because when the dose is large, or the remedy long continued, the initial stimulation will be followed by depression. The basis, therefore, upon which cellular therapy rests, is that of stimulation without irritation, which can be accomplished by the selection of the proper remedy and regulation of the dose.

This brings us to consider the *vis medicatrix naturæ* as a factor in resisting disease, really nothing more than a supposititious entity until within the recent past, when we have begun to fathom the mystery of cell function and cell-life.

In order to render comprehensible what follows, it will be necessary to recapitulate some of the more important conditions dependent upon cell function essential to the enjoyment of health; and this will afford, by reflection, a bird's eye view of the so called *vis medicatrix naturæ* as it is now understood. To maintain good health a person should have a sound digestive apparatus. This trite observation has more significance than would appear at first sight, owing to the important changes which occur after the ingestion of food, changes besides those incident to the conversion and absorption of the different kinds of food stuffs. Reference is had to "digestive leucocytosis"—we may call it a vital process—a phenomenon characterized by the rapid multiplication of the white blood corpuscles, a peculiarity which was also noted by Professor Virchow. Slightly modified, many of these leucocytes become active agents in the destruction of micro-organisms and their products. They enact the *rôle* of scavengers, and are freely distributed throughout the system along with the red blood-copuscles which carry oxygen to every part.

By way of digression, it may be mentioned that this function of the red blood-corpuscles is essential to the welfare of the tissues. The oxygen is taken up by the protoplasm, which in turn gives off carbonic acid and other waste-products, and loaded with this burden the little cells return to the lungs, discharge their cargo, and again take a new supply of oxygen. It is unnecessary to dwell upon this peculiar and interesting function, known as internal respiration, except to note, in passing, the use made of the oxygen by the protoplasmic cells. In the first place, they act as storage-tanks, giving off the gas as required to keep up the functional activity (combustion); in the second place, they can convert this gas into ozone, which is far more active than the oxygen itself.

The presence of oxygen in the blood, in the protoplasm, and in the intercellular fluids is not in itself sufficient to maintain the tissues and fluids of the body in a thoroughly antiseptic condition, owing to the active tissue-change, along with the production of waste products. It remained, therefore, to discover the causes at work which enabled the system to resist disease, and scientists have been richly rewarded by their investigation of the function of the white blood-corpuscle. From present indications this discovery promises to become the missing link in the so-called *vis medicatrix naturæ*, as will presently appear. More than ten years ago Professor Metschnikoff taught that leucocytes or phagocytes performed an important service to the human organism, namely, that they enveloped or surrounded bacteria and destroyed them as well as bacterial products. Within the past year, however, several scientists have demonstrated that leucocytes, through their nucleus, produce a phosphorized proteid termed nuclein, which possesses active germicidal properties. These researches covered not only the test-tube observations, but experimental studies upon animals, and showed conclusively that solutions of nuclein employed in seasonable time would confer immunity against disease, and thus a new factor was added to the modern idea of cellular therapy, that of nuclein therapy.

The development of this modern idea in scientific medicine, as will be apparent from the foregoing brief sketch, is but a question of time, since it hinges altogether upon actual facts, speculative hypotheses being kept entirely in the background. Even now, clinicians and experimental physiologists are earnestly at work in the expectation that they can further advance the art of healing, and doubtless, ere long, we shall have the satisfaction of asserting that practical medicine is really in fact, as well as in name, scientific medicine.

1421 Walnut Street, Philadelphia, Pa.

REPORT OF COMPLICATED CASES INVOLVING UTERUS, TUBES, AND OVARIES, TREATED SUCCESSFULLY; WITH A PLEA FOR CONSERVATIVE SURGERY IN DEALING WITH THESE APPENDAGES.

By PAUL OUTERBRIDGE, M.D.,

ATTENDING GYNECOLOGIST AT NEW YORK CANCER HOSPITAL; ACTING ATTENDING GYNECOLOGIST AT WOMAN'S HOSPITAL OF NEW YORK; ATTENDING PHYSICIAN AT NEW YORK LYING-IN ASYLUM; ATTENDING GYNECOLOGIST AT DEMILT DISPENSARY; MEMBER OF NEW YORK OBSTETRICAL SOCIETY; MEMBER OF HOSPITAL GRADUATE SOCIETY; MEMBER OF ALUMNI ASSOCIATION OF NEW YORK HOSPITAL; MEMBER OF ALUMNI ASSOCIATION OF WOMAN'S HOSPITAL, ETC.

This subject is one that demands special attention from the gynecologist of to-day, for operators, although more careful at the present time than for years past, are still prone to remove tubes and ovaries that, in my opinion, could be retained by the patient to very great advantage, if given a chance through conservative surgery to regain their functions. There are, of course, cases of salpingitis which time alone will cure; others that can be and are relieved by the various non operative and conservative methods advised by the specialist; and still others in which abdominal operative measures, either radical or palliative, are imperative to effect a cure.

Now it is not to the first class of cases that I purpose to devote this paper, but to those in which laparotomy is indicated.

Dr. Polk, of this city, deserves the greatest praise for the pioneer steps taken by him in calling our attention to the importance of saving the uterine appendages in cases requiring laparotomy, and in which there is the slightest chance of being conservative. Martin, of Berlin, was also one of the first to call attention to this point. Their work was brought to our attention about four years ago. Dr. Thomas, I believe, has also advocated

the same doctrine and reported as cured cases which required abdominal section, and in which the tubes were not removed, but simply the adhesions were freed and the tubes and ovaries left. Since first hearing Dr. Polk's remarks on this subject, I have made it a practice to save wherever it seems practicable to do so. I am very sorry to see that he at present advises removal of the uterus when the tubes are removed.

I have come to believe, after studying carefully the various cases, both with and without the presence of the menstrual function, that menstruation is essential to a woman's comfort and happiness. In the lower animals we find few if any superfluous organs, and when we contemplate the nervous system of mankind, the complicated and delicate adjustment of which renders it all the more sensitive to interference, we cannot but regard it as essential that the human being should remain intact in the matter of organs exercising a powerful influence on the nervous system. Yet many operators assure their patients that the deprivation of the menstrual function will be attended by no discomfort or loss of happiness, but merely by sterility.

A statement in detail of the symptoms of patients suffering from the effects of loss of the appendages is impracticable within the limits of this article, but I hope at some future time to treat more fully of the matter. Meanwhile I will confine myself to reporting cases in which laparotomy was essential, but in which tubes and ovaries were allowed to remain.

The first, a Mrs. L——, of Brooklyn, was examined by Dr. Bushong, who is associated with me at the Demilt Dispensary, and myself. The uterus was firmly fixed, retroflexed, the tubes and ovaries matted to its side and behind it. The course of treatment followed was several weeks' local tamponading and counter-irritation by Monsel's solution. Finding that this could not relieve, and that it was, in fact, entirely inadequate, I advised strongly that she go to the hospital and submit to operative measures. She seemed reluctant to lose the appendages, but expressed perfect willingness to undergo the operation when informed that the appendages would not be removed unless their removal should be absolutely essential.

The patient was thirty-eight years of age, married, had had two children the last six years before operation. She entered the New York Cancer Hospital, February 4, 1890, and had operation. House staff assisting. Median incision. Uterus retroflexed, bound down, tubes enlarged, congested, and their numerous adhesions aided in holding the uterus down. Ovaries at first could not be found, as the whole pelvic viscera were matted together. All the adhesions were carefully separated by manipulation. The right tube was very much enlarged, and at its fimbriated extremity did not seem pervious. Its canal was entered by cutting in line with the tube toward the uterus. This was laid open for about one and a half inch, and as there was a thin and slightly purulent discharge present within the tube, it was thoroughly cleansed with hot water and a sponge. There was very little hemorrhage. After this a probe was passed down through the tube into the uterus without difficulty. Thorough irrigation was done, and one catgut suture was put in at uterine end of the tubal incision. The left tube was in about the same condition, except there was no purulent-looking fluid, and it was incised in a similar manner; but no probing was attempted, and no suture applied. The ovaries were enlarged and hardened, containing a number of small cysts which were incised with knife, permitting thorough escape of all fluids contained in them. The uterus and appendages now assumed a normal position, but fearing that they might again become attached posteriorly, I stitched the round ligaments to the anterior abdominal wall with four catgut sutures, two on either side. The stitches were taken about half an inch from the uterus, the gut being of a kind that would hold for at least five days. The abdominal wound was closed with usual silk-worm sutures. The uterus at this time was thoroughly forward and held there by the the sutures in round ligaments. Patient had a little tenderness over abdomen, liver, and pelvis for a few days, with some rise of temperature. Bowels were moved third day, as is my custom, with salines. Patient went on and made good recovery, being discharged, with uterus in good position and slightly movable, on March 2, 1890. Two years afterward she became pregnant and came to see me at the dispensary several times during the carrying term. She seemed to carry the child very comfortably. The adhesions formed by suturing the round ligaments to anterior abdominal wall never seemed to cause the slightest trouble. I am curious to know whether the adhesions still exist and are simply stretched, or whether they gave way completely during the ascension of the uterus.

She gave birth to a child January 16, 1893, and Dr. Fulda, of 107 Kent Street, Brooklyn, attended her. She says that the labor was a natural one. The uterus is now in the natural position.

In a similar case, where the patient had never had children, I operated, in 1890, at the Woman's Hospital. In this instance all adhesions were loosened, the tubes cut up, cleansed, etc., and the uterus was held forward, the round ligaments being stitched to the anterior abdominal wall. The patient made a good recovery, though she complained of pelvic pain and had a profuse uterine discharge for some time after the operation, for which she was treated locally until it cleared up. This was undoubtedly a gonorrhœal case. The uterus is now in good position and the patient free from pain, though she has never had children.

Case three, unmarried. Done at Woman's Hospital the past summer. In this case suspected gonorrhœa to be cause of retroflexion and adhesions. Patient had been in hospital a long time, complained of much pain, had recurrent attacks of pelvic peritonitis, and did not improve with treatment. Laparotomy performed. Considerable ascites in abdominal cavity, adhesions all broken up. Uterus held forward by stitching round ligaments to anterior wall. In this instance tubes were not divided and thorough curettement was not done, although it is my custom to do it thoroughly in cases where I suspect gonorrhœa. The uterus was held in good position by operation. Patient did very well indeed for ten days, when, three days after removal of sutures a small abscess appeared in the lower end of the abdominal wound. This was opened at once, and within a few days there developed phlebitis of right leg and she was confined to her bed for some weeks. The position of the uterus was, however, good, and the organ fairly movable. In this case I believe there must have been some infection of the tubes beforehand. I am not aware of the present condition of this patient, but I am not inclined to believe that she has been perfectly relieved. Probably another operation will be necessary to effect a cure.

In dealing with the uterus itself it is also well to be most conservative, and at present we are, I think, too much given to extirpation for a simple fibrous growth of the organ, and even a simple pyosalpinx.

I do not wish to convey the idea that I do not believe in extirpation of the uterus when there is any suspicion of malignancy, or even when the uterus is riddled with pus, for my views in these cases are radical. Immediate and thorough removal of the uterus and all available tissues, is then, in my opinion, the only proper course to pursue. I should like, however, clearly to express myself as being utterly opposed to removal of uterus for a small, simple fibroid, or for a pyosalpinx, unless the uterus itself is thoroughly riddled with the germs. In support of this position I refer to several cases in which a cure has apparently been effected.

Case I.—Mrs. M——, private patient of my friend Dr. J. A. Campbell, with whom I saw patient, in consultation, October, 1892. The case had been previously diagnosed by us, and, after consultation, we concluded to remove the fibroid, and, if possible, without removing

uterus or ovaries, as the patient was most anxious to have children. Laparotomy was done, Dr. Campbell assisting me, early in November, 1892. A large fibroid, weighing six and a half pounds, was removed from the fundus of uterus, care being taken to dissect off the peritoneal coat and turn it over or back. After this was done a curved scissors was used in cutting off as much of the surrounding tissue as possible. In fact it was removed down to uterine tissue. Then the peritoneal flaps that had been sewed were sutured over with a continuous silk stitch, thus covering the raw excavated surface. The ovaries and tubes were fairly normal and were left intact. Another small fibroid, about the size of a small egg, was removed. Patient made an excellent recovery under Dr. Campbell's management, and within a few days Dr. Campbell has reported to me that the patient is pregnant about seven months, and is apparently in first-class condition.

Case II.—Mrs. C——, operated on June, 1893, at Cancer Hospital. Large fibro cystic tumor of ovary and tube, weighing about eight pounds, and consisting principally of solid fibrous tissue, with small, broken-down cavity in its centre. This stump was very large and was treated similarly to the one just mentioned. Patient made a good recovery, and has gained about forty pounds since the removal of the tumor. She is now perfectly well.

I must confess that in this last case my first thought was to extirpate the uterus also, but I believe the woman is very much better for having the uterus and other appendages left. I have shelled out a number of fibroids from uterine wall by doing laparotomy first, then cutting into the uterine wall and shelling fibroid out. After which the two uterine edges are stitched together with continuous catgut or silk suture. My results in a considerable number of these cases have been invariably good, and I can unhesitatingly recommend this procedure.

I have, in addition, removed a number of large fibrous growths from broad ligaments, the first about two years ago in private work, and the last very recently at the Cancer Hospital. The growths ranged in size from a small orange to a man's fist. In most of these cases the tubes and ovaries were apparently normal and were left. But in the last case the tube and ovary on the side where the growth was situated were removed, as they were bruised rather much in the removal of the tumor, which, as can be easily understood from the situation in the broad ligament and extending down below the cervix, was very difficult indeed to remove without removing the uterus and all. All these cases have been satisfactory, and the last one will, I believe, prove a success in every way.

I have also operated successfully in a number of ligamentous cysts. In most of these I have been successful in saving the tubes and ovaries. Much care is always taken, after the removal of the intra ligamentous cysts and fibroids, to stitch the divided surfaces of the broad ligaments together, thus preventing many adhesions and much inflammatory exudate; in other words, leaving the pelvic organs in as normal a condition as possible.

A good rule in conservative surgery, or in abdominal surgery of any kind, is to cover all denuded surfaces wherever there is available tissue with which to do it.

In closing, I would say that as soon as the abdominal cavity is opened, and before systematically attempting removal of any abdominal or pelvic growth, it is of the highest importance, in every case, to make an exact diagnosis of the appendages, uterus, and, in fact, of the general abdominal cavity.

Further, it must never be forgotten that to be conservative in the matter of removing organs that can be saved is the highest and most advanced surgery.

The Medical Officer of Health to the City of London receives a salary of $7,500, and an additional sum of $1,000 as analyst; but he is obliged to give his whole time to the duties of the office.

A CASE OF CHRONIC PERITONITIS, WITH INTESTINAL AND ABDOMINAL FISTULÆ—ENTERORRHAPHY—RECOVERY.[1]

By FREDERICK HOLME WIGGIN, M.D.,

PRESIDENT OF THE SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL; VISITING SURGEON TO THE CITY HOSPITAL, GYNECOLOGICAL DIVISION.

The three great dangers the surgeon has to encounter in dealing with the abdomen and its viscera are sepsis, hemorrhage, and intestinal adhesions. Of these the last is by no means of the least importance. When not causing immediate death by intestinal obstruction, it frequently defeats the object of surgical interference—the complete restoration of the patient to health; and in many cases, while removing the danger of sepsis, it substitutes that of intestinal obstruction; while the pain is relieved for a short time only, if at all.

The attention of the writer was forcibly drawn to this subject, some years since, by the inspection of an abdominal cavity and its contents in a patient who had died of intestinal obstruction twelve months after an apparently successful operation for pyosalpinx. This examination revealed such extensive adhesion of the intestines that the question arose whether the patient would not have been better off if the original operation had not been performed. The conditions found would have made an operation for the relief of the obstruction, which was by a band low down in the pelvis, impossible. The operation was performed in strict accordance with the technique of the day, and was not followed by any signs of sepsis. The wound healed primarily, the patient's bowels moved early, and in fact she made a rapid recovery. But although her sepsis was relieved, her pain soon returned, and she had at short intervals recurring attacks of intestinal obstruction which were easily overcome by mild measures. Finally, being away from her home when an attack of intestinal obstruction came on, her physician, ignoring her previous history, gave croton-oil and other cathartics; the violent peristalsis induced forced such an amount of gut under a band that it became strangulated, and after some days' delay it became gangrenous and perforated, with a fatal result. A similar history has followed successful operations of this nature so often that the question is frequently asked, Does surgery do what it claims—cure the patient?

The gynecological service at the City Hospital receives, for one reason or another, many cases that have had cœliotomies performed at other New York hospitals, which have eventuated in adhesions, sinuses, and ventral herniæ. They are sent here for secondary operations, having been probably reported in good faith by the operators as "successful" cases. It is for the purpose of calling attention to this subject of intra-peritoneal adhesions, and to offer a suggestion for their prevention, as well as to provoke discussion, that the report of the following case, which has given the title to this paper, is of interest.

A. W——, a female, about twenty-three years of age, was admitted to the Penitentiary Hospital on Blackwell's Island, April 27, 1892. Her history previous to coming under my care in February, 1894, is as follows: She said that after her first menstruation, which took place at the age of thirteen years, she had had an attack of spinal meningitis, and had not menstruated again for two years. Then menstruation had gone on regularly, and had been of the tri weekly type. It had been profuse, lasting seven days, and being accompanied by much pain. She had had no children. One miscarriage at five months had occurred during the summer of 1891. Soon after this she had had a syphilitic eruption, with pains in her bones and an iritis. During the winter of 1890–91 she had had a localized pain in the left inguinal region, which had been more severe at the menstrual periods. There had also begun to be difficulty and pain on defecation.

[1] Read before the Fifth District Branch of the New York State Medical Association, at its Tenth Annual Meeting, held in Brooklyn, May 22, 1894.

In the autumn of 1891, she had received a kick over the seat of pain, and after this the pain had become worse, and had been accompanied by constant headache and nausea. She had then become addicted to the use of morphia and cocaine. Her bowels had moved regularly. It is noted in the hospital records that a vaginal examination, made in May, 1892, showed her uterus to be slightly anteflexed, enlarged, and tender, with a pin-hole os, and the left ovary to be somewhat enlarged. Again, on November 30th, a vaginal examination revealed the left ovary enlarged to the size of a hen's egg, and also a salpingitis of the right tube. Rectal examination disclosed a stricture at two inches from the anus.

On December 14, 1892, the rectal stricture was incised and divulsed, and on January 6, 1893, a cœliotomy was performed, and both tubes and ovaries removed. In breaking up the adhesions about the right tube, it was ruptured, and some yellowish pus escaped into the peritoneal cavity. It was removed by sponges wrung out in a 1 to 20 carbolic acid solution. No further particulars are given except that the wound was closed by silkworm-gut sutures passing through all the layers. Primary union occurred except at one point, near the lower angle of the incision. A week after the operation a probe was introduced at this point, and pus welled up from the wound. On the fourth day after the operation there was a free escape of pus from her rectum. Notwithstanding her sepsis her bodily temperature did not rise above 100°, and no antipyretics were used. On August 14, 1893, it is recorded that the sinus still persisted, and that the patient was suffering much pain. A secondary cœliotomy was performed by the surgeon on duty. After the incision had been made, so many and firm adhesions were found that the wound was closed without any further interference. After the wound had healed, the sinus remained patent, and the former symptoms continued unabated. A vaginal examination made in December, 1893, revealed a large tumor on the patient's right side, which was very painful. The propriety of an operation was considered, but before it was done there was a free discharge of pus per rectum, and the tumor subsided.

On taking charge of this service, February 1st of this year, I found this patient in a deplorable condition, suffering from continuous pelvic pain. Examining her with one hand on the abdomen and the other in the vagina, a decided resistance and fulness were encountered, and there was marked tenderness in the right iliac fossa. The uterus was fixed. The sinus at the lower angle of the old cicatrix was patent, and discharged pus. A rectal examination revealed a stricture of large calibre, and an ulceration at two inches from the anus. The patient earnestly requested that something be done for her relief. After careful consideration of the case, operation was decided upon, and performed on February 14th.

The incision was made in the line of the old cicatrix, splitting the sinus, which was found to pass into a cavity formed by adhesions of the intestines to the anterior abdominal wall, to themselves, and to the uterus, and bounded in front by the bladder. Into this cavity was poured a fifteen-volume solution of hydrogen dioxide, and after this had been allowed to remain for a few minutes, it was sponged away and the adhesions broken up. As the intestine was freed from the right side of the uterus, a fistulous opening was discovered, which was closed as soon as the intestine had been sufficiently freed to allow of its being brought outside of the abdomen. This closure was effected by scarifying the peritoneal coat of the upper side, the lower side being already denuded, and by introducing a single row of Lembert suture. The appendix was adherent low down in the right iliac fossa, and was freed, but not removed. After the adhesions which formed this abscess cavity had been broken up the intestines were found to be very much tangled and matted together. These adhesions were broken up partly by the finger, and partly by dissection. The omentum, which was adherent, was ligated and removed. At one point the peritoneal coat of the intestine was ruptured over an area measuring $\frac{1}{4} \times \frac{1}{2}$ of an inch. It was repaired by Lembert sutures. The hydrogen dioxide was freely poured into the peritoneal cavity, and after a little delay, the cavity was flushed with normal salt solution (0.6 per cent.), and the cavity left full of the same. The temperature of the solution was 115° F. The edges of the old sinus were scraped with the sharp spoon, and the wound closed with silkworm-gut sutures passing through all the layers. No drainage was employed. The time occupied by the operation was two hours. Only eight ounces of ether were used, but the patient took the ether badly, and this much prolonged the operation. Although suffering from shock, she rallied well on the introduction of hot saline solution into the abdominal cavity, aided by the hypodermic injections of glonoin and strychnia. Her bowels moved shortly after the conclusion of the operation, and again on the third day, although morphia was employed more or less freely. No cathartics were given after this, her bowels moved regularly several times a day. The patient had very little nausea. Beef peptonoids were given within twelve hours after the operation, and were followed by peptonized milk and semi liquid food on the fourth day. Her temperature, pulse, and respiration became normal on the sixth day. Her pain was relieved. The wound healed primarily throughout. Following the operation, there was a decided improvement in her general appearance. On March 20th, it was noted that she was in better health than she had been for two years previously. A vaginal examination at this time showed the uterus to be freely movable. There was no evidence of adhesions or of tenderness in the pelvis. Six weeks after the operation the patient was in sufficiently good condition to submit to the removal of three inches of her rectum, and she is now in good health, with the exception of some nervous disorder.

As the technique has been alluded to, it may be well to state that in this, as well as in all other abdominal operations performed within the past eighteen months by the writer, all chemicals except hydrogen dioxide have been avoided, reliance being placed entirely on sterilization of instruments by boiling, and on the use of sterilized salt solution, with the avoidance of the use of sponges. The main point of interest in this case, aside from the number of cœliotomies submitted to by this patient, and the severity of the last one, is the free use of the hydrogen dioxide for the purpose of destroying the old abscess cavity before breaking up the adhesions, and the closing of the abdominal cavity after filling it with the saline solution, for the definite purpose of preventing the formation of new adhesions. Further experience gathered during the past winter has confirmed the claim made in a former paper, that closing the abdominal cavity after filling it with hot sterilized salt solution, lessens shock, prevents the formation of adhesions, aids in the readjustment of the intestine and omentum to their proper position, and lessens the danger of septic peritonitis. To this I may add that after operations where it is so used there is little nausea, and an absence of the insatiable thirst which formerly tormented these patients, and that the bowels act more freely, often of their own accord, in spite of the fact that morphia is used whenever indicated on account of restlessness. My opinion is confirmed in the belief that hydrogen dioxide is a safe and sure disinfectant for the peritoneal cavity. I have used it with satisfactory results in more than twenty cases.

In conclusion, I would like to call attention to the fact that, although the duration of the operation was two hours, only eight ounces of ether were used. The shock following an operation is, in my experience, more dependent on the amount of ether employed than on the duration of the operation, although this is of importance. Had not experience given me faith that by the use of salt solution adhesions once broken up could be prevented from reforming, that in hydrogen dioxide there is a safe and certain weapon for preventing and overcoming sepsis in the peritoneal cavity, and that with the

closed ether inhaler a long operation could be performed with the minimum amount of ether, and therefore with little shock, the above described operation would not have been justifiable, and would not have been undertaken.

55 West Thirty-sixth Street.

INTERNAL URETHROTOMY FOR STRICTURE.

By T. E. SCHUMPERT, M.D.,

SHREVEPORT, LA.

SURGEON SHREVEPORT CHARITY HOSPITAL, AND MEMBER NATIONAL ASSOCIATION RAILROAD SURGEONS.

In discussing the treatment of stricture of the urethra this paper concerns organic stricture only; but before entering upon its treatment proper, we will recapitulate briefly the pathology of stricture, and look casually at the anatomy of the penis; by so doing we will be better able to treat intelligently this disease. Its idiopathic etiology in vastly the majority of cases is gonorrhœa, though we do have some cases from traumatism to the perineum or urethra, by say a kick, a fall astride a box or fence, a bruise while riding bare-back, or on the horn of a saddle, by the use of imperfect instruments, or breaking one in the urethra. It is claimed by some, too, that strictures are caused by too strong injections. I believe it is possible to make an injection strong enough to produce a stricture by using some very powerful caustic, but in meeting the indications of a gonorrhœa, this is but rarely if ever done, the subsequent stricture to these gonorrhœa injections being only coincident. I use at pleasure for cystitis a ten, fifteen, or even twenty grain to the ounce argent. nitrosæ solution, injected into the bladder after a thorough catheterization, and allow the patient to void it through the urethra, without any evil effects. It is what, then, that produces it in gonorrhœa? The urethritis *per se*. Eighty five per cent. of all strictures are so caused.

The male urethra is about eight inches long, and divided into the prostatic (one and one-half inch), membranous (three-quarter inch), and spongy or pendulous portion which occupies the remainder of its length. It is flexible and of an unequal breadth at each of the different divisions, being broadest at the prostatic, narrower at the spongy, and narrowest at the membranous portion, and any portion of the urethra that is not dilatable is strictured. The urethra is related to the corpora cavernosa as a ramrod is to the barrel of a double-barrelled shotgun, the corpora cavernosa incorporating about one-third the circumference of same when distended, with its sides not in apposition as the meatus would seem to indicate, but the roof and floor kiss each other in perfect co-aptation.

Stricture may be of such a mild type as only to involve a thickening of the mucous membrane, or the inflammatory process may lead out and invade the delicate erectile tissue, thereby causing a proliferation of the connective-tissue element and an increase in the thickness, density, and non-elasticity of this membrane at the site of stricture, which may be single or multiple. This pathological process takes place just beneath the mucous membrane, and not on its surface, as was formerly believed, and as the stricture grows older this transverse non-elastic band grows tighter and contracts more firmly. We have linear, annular, and tortuous strictures. They are also divided into passable and impassable, according to their degree of perviousness to a filiform bougie; of course, if this instrument can be made to enter, it falls under the former class, but if this be impossible, under the latter.

About seventy-five per cent. of strictures are single. Otis places the location of the majority of strictures within one and one quarter inch of the meatus, the next most common site being about the middle of the pendulous urethra. Thomas has failed to find in two hundred and seventy autopsies, or in any patient, a prostatic stricture, *i.e.*, a stricture within one and a half inch of the bladder, that portion also which lies beneath and behind the arch of the pubis, and which therefore from the field of operation is most obscure and difficult of access. Walsh found in one hundred and eighty-five cases one stricture of the membranous urethra that involved also a portion of the prostatic urethra, so we may very safely eliminate this portion of the urethra from the stricture field; and the fact that this can be done is but another trace of the Almighty's wise and sympathizing hand, for even though he has rightfully cursed the nation with this malady, he places it within comparatively easy reach of the surgeon. Strictures do occur, however, sometimes as far back as the posterior membranous urethra, *i.e.*, four and one-half to six inches from the meatus.

It is a popular idea with the majority of our profession (prejudiced by results antedating antisepsis) that the cutting operation should be the last resort, that it should be used when all else has failed, as the last alternative, and the instruments recommended for this little operation are almost too numerous to mention; but among the most prominent are filiform bougies, bougies not filiform, sounds, guides, probes, rapid dilators, urethrotomes, directors meatometa, urethrometa, bistouries, etc. I think the reason the average practitioner doesn't operate on his own cases, but instead takes them to a surgeon or a specialist, is because whenever the patient is presented the operator shoves under the practitioner's nose such an elaborate display of mysterious instruments, all of which the latter, without thinking, believes to be necessary to make the examination or perform the operation, that he himself is humiliated, and the magnitude of the operation proportionately exaggerated. I have a record of thirty-nine urethrotomies performed by myself, thirty five of which were internal, including four impassable; the remaining four were external urethrotomies. The latter were among the first operations on the urethra that I ever did; they were two with and two without a guide, one of which gave me as much trouble during the performance of the operation, and caused me as much apprehension during the after treatment, as any surgery I have ever participated in. I have since become so impressed in favor of the internal operation that I have never yet had occasion to return to it again. I have treated a great many strictures by dilatation, but so far as my experience goes it has only been palliative, for most invariably the patient would return again during the course of a few years with his same old trouble, notwithstanding the fact that he had been taught and ordered to use the bougie himself once or twice a month. This was not done, of course, or it could not have possibly closed; but at the same time, as long as it is necessary to use an instrument this disease cannot be considered cured. I find that internal urethrotomy gives the best results and is justifiable in any case occupying the pendulous urethra, and all strictures that I have yet seen in this locality are accessible by the method which I am about to detail, which requires a set of sounds, a bistoury, grooved director, and a set of bulbous bougies or urethrometer; this latter instrument, however, is not essential, though it may often be used very conveniently in locating strictures and testing their extent. It, at any rate, is a very ingenious little instrument, and reflects credit on its inventor, Professor Otis. It is generally conceded by the profession, I believe, that bougies or sounds should be used if it be possible to pass one; if repeated efforts be made without avail, however, then external urethrotomy as the last alternative must be resorted to; but before proceeding with this cutting operation, while the patient is yet under the anæsthetic, they say another attempt must be made at introducing a filiform bougie, which, if successful, defers the operation perhaps indefinitely. For an external urethrotomy it is best to make an incision two and a half or three inches long, and the greatest precautionary measures must be observed if performed without a guide, else serious damage might be inflicted; the wound is then left to heal by granulation. All impassable strictures are said to be suitable cases

for this operation, but none else. The wound made in an external urethrotomy is necessarily large, the operation a long and tedious one, two hours at times may be employed in performing it, fever runs high; it is with difficulty the patient is kept clean, and the operation is not at all free from danger. Wyeth, Otis, Thompson, and quite a number of others have invented instruments for internal urethrotomies; these instruments are necessarily large, heavy, and therefore cumbersome; the blade of none of them extends beyond the shaft, and therefore are not intended for impassable strictures; they do beautiful work, however, on strictures admitting a No. 7 sound.

The bistoury which I use has a perfectly straight shank, seven inches long, with a blade extending from its point one-half inch back, and presenting not exceeding one-quarter of an inch beyond the front surface of the shank; the back of the blade is exactly on a straight line with the back of the shaft, even to its point. My grooved director is seven inches long and fork shaped, with the handle of the fork representing the groove of director and the prongs the handle; it is made of sufficient strength to admit of considerable pressure without bending; the strength of the director, however, must not lie in its back, but sides only, as the back must be thin in order to allow the back of the knife to approach as nearly as possible the roof of the urethra, thus enabling the operator to incise the stricture through its entire diameter. Now, the patient having been placed in the usual position, and a stricture diagnosed, if it be meatal surgeons all agree that it should be cut with a bistoury, and in this locality a director is not indicated; but if it be lower, this latter instrument becomes imperative. With the grooved director and bistoury which I have described, all pendulous strictures have fallen in the field of internal urethrotomy and easily available. The penis is held at right angles to the body with the left hand of an assistant, while with his right he holds the director firmly against its roof, with the groove of director presenting toward the patient's feet, the penis in the meanwhile being kept somewhat extended. If the stricture be passable, the operator then, with the bistoury in his right hand, glides it down the director until in the locality of the stricture, this point being marked by the thumb and second finger of his left hand, which press gently the sides of corpora cavernosa in aiding to keep it perfectly steady, while the index finger is held in the same locality but against corpora spongiosa to direct the blade of the knife, which may plainly be felt as it cuts through the stricture, first in front, then on either side. If the stricture be impassable, the director is introduced until its blunt end comes in contact with the face of the stricture, the penis being held as before if in the upper pendulous portion; but if lower and possibly in the anterior membranous urethra, after the director and knife have been introduced beyond suspensory ligament, the penis is tilted forward to an angle of about 45°, the director pressed firmly in the direction of symphysis pubis and downward until in contact with the stricture; the knife is now pressed well back against the director, then downward until the resisting stricture yields; three incisions are then made as before described. By actual experiment on the cadaver, I find that I am able to reach in most cases by this means the membranous urethra. This operation is extremely simple, very easy, and usually requires but five or ten minutes, is performed with a very limited, inexpensive outlay of instruments, and I never expect an untoward result; is more cleanly, as the urine is voided per viam naturalem instead of through a vicarious passage in a very clumsy location. The main points to be guarded are, first, to have a reliable assistant, who will hold the penis and director perfectly steady and exactly as directed by the operator, who must himself see to it that the end of director is in contact with face of stricture, that it is in perfect line with the penis, and be very careful to pass his knife exactly in that line. After-treatment consists in first washing out the urethra with peroxide hydrogen, then injecting copiously with gr. vj. to ℥ j. of boracic acid; this is done seven or eight times during twenty four hours, until all discharge ceases, and a large sound introduced once in four or five days for the first month, once a week the second month, once in two weeks the third, and during the next two months twice or three times ought to suffice. I usually, at the same time, put the patient on some alkaline diuretic, santal midy being my preference, which is also an astringent antiseptic, having special action on mucous surfaces. In conclusion, I would like to say that I have succeeded in passing filiform bougies that had resisted repeated previous attempts, by instructing the patient to allow his bladder to become distended with urine, then thoroughly cocainizing the urethra and allowing him to void his urine while the attempt is being made; this method is especially applicable to cases of valve stricture. In doing an external perineal urethrotomy once (without a guide) that was baffling entirely my skill, I found that much aid was given by the introduction of a bougie from behind after a suprapubic cystotomy had been performed. I cut strictures indiscriminately as regards to class, and always in three directions; a sound corresponding with the full capacity of the urethra should be used at once. This operation may be performed with pain reduced to a minimum by the use of cocaine and Bumstead's deep urethral syringe. The incisions must be made in the long axis of the penis; when they heal, they do so with an elliptical patch for each incision, thus increasing the calibre of the urethra by the insertion of a new-formed tissue which is pathologically different to that of the stricture. It intercepts the force of this contracting band and establishes another in a direction that rather favors the normal calibre of the urethra.

Clinical Department.

A CASE OF NON-HEREDITARY FRIEDREICH'S DISEASE.[1]

By CHARLES E. NAMMACK, M.D.,

ATTENDING PHYSICIAN TO NEW YORK HOSPITAL, OUT-PATIENT DEPARTMENT.

After the elaborate critical digest of Ladame,[2] supplemented as it was by the scholarly article of Byron Bramwell in his magnificent "Atlas of Clinical Medicine,"[3] it would seem that little could be added to the literature of Friedreich's ataxia. Yet, Bramwell states that very few isolated cases have been recorded, and thinks it "not unlikely that the isolated cases (cases in which only one member of the family is affected) pass unrecognized." This view is shared by Ladame, and emphasized recently by the publication of an isolated case by Hector Mackenzie,[4] who states that the alternative title, hereditary ataxia, for Friedreich's disease may have something to do with preventing its due recognition.

Eight days before the writer saw Mackenzie's article, a little girl was brought from Yonkers to the New York Hospital with the following interesting personal history:

Mary B——, aged fourteen, born after a normal labor, began to have unsteadiness in walking when she was five and a half years of age. Previous to this time she had an attack of measles at the age of two and a half years, a second attack of measles while it was prevalent in the family at her fifth year, and six months later had scarlet fever, followed by the unsteady gait. Her parents think that diphtheria did not accompany the scarlatina. Her gait has become progressively worse since. Some time after the development of ataxia in her lower limbs, she was annoyed by jerky movements of hands and arms when writing, and was finally obliged to leave school. She had headache every morning, and occasional shooting pains in her legs. She has had nocturnal enuresis since infancy, but lately has been troubled by incontinence in the daytime also. Her case has been variously

[1] Presented at the New York Academy of Medicine, Section on Pediatrics, April 12, 1894.
[2] Brain, 1890.

[4] American Journal of the Medical Sciences, April, 1894

diagnosticated as diphtheritic multiple neuritis, chorea, precocious locomotor ataxia from inherited syphilis, etc. This is not surprising when we reflect that Friedreich's ataxia is one of the rarest of all known forms of nerve diseases, that the great majority of medical men have never had the opportunity of seeing it, and further, that they do not expect to meet with it in an isolated form.[1]

This child's family history is unusually good. She is the oldest of seven children. One baby died at five months of "inward spasms due to teething." The other five are living and healthy. Both parents accompanied her to the hospital and were apparently perfectly sound and healthy. Three other children in the family have now passed the age at which the unsteady gait began in Mary, without showing any symptom of it, although their immunity cannot be guaranteed from this, as stated by Soca.[2] Many exceptions to the rule formulated by him are on record.[3] Neither parent knew of any neurotic or degenerative tendency among the grandparents, uncles, aunts, or cousins, except that one paternal aunt died at the age of twenty-two of "consumption of bowels," after an illness of three years. Another paternal aunt died of endocarditis, contracted during the blizzard of 1888. Four aunts and uncles are living and well. Consanguinity did not exist between Mary's parents, nor had either ever suffered from alcoholism, Bright's disease, or syphilis. The writer considers it improbable that her conception might have occurred while either parent was under the influence of alcohol. Mother has had no stillbirths or miscarriages. There is no knowledge that any near relative has ever been ataxic or club-footed.

	Age if Living	Condition of Health.	Age at Death.	Cause of Death.	How long Sick.
Father	39	Excellent.			
Mother	37	Excellent.			
Brothers, Francis	2	Excellent.	5 mo.	Convulsions?	1 day.
Brothers, Joseph	4	Excellent.			
Sisters, Mary	14	Friedreich's Disease.			8½ yr's.
Sisters, Alice	12	Excellent.			
Sisters, Rose	10	Excellent.			
Sisters, Anne	8	Excellent.			
Father's Mother	77	Excellent.			
Father's Father	80	Excellent.			
Mother's Mother	76	Excellent.			
Mother's Father			53 yr's.	Pneumonia.	10 d'ys.

The symptomatology of the case at present is as follows: The gait is very unsteady and rolling in character, and child is unable to stand with the eyes closed. Muscular power in the legs is good, considering that the child cannot actively exercise. Dynamometer records thirty in right hand, and twenty-two in left hand. Hand grasp seems almost as strong as in other children of her age. The knee-jerks are absolutely lost. She has some ataxia in the upper limbs, but can thread a needle, and her manner of picking up a needle from the table has not the so-called "bird of prey" movement.[4] She presents the characteristic foot deformity of this disease. Each foot is stumpy and short, and appears to be compressed from before backward in the antero posterior diameter. The instep is highly arched and the dorsum of the foot very prominent. The first phalanges, especially of the great toe, are over-extended and the tendons of the extensor proprius pollicis muscles stand prominently out. The feet are cold, and of a purplish color. Lateral curvature of the spine is present. The speech is low-toned, monotonous, and harsh, but not "scanning," as in multiple sclerosis. Nystagmus is evident when eyes are moved laterally or upward, or when the object is fixed.

Pupils are equal, of medium size, and respond both to light and to accommodation. No oculo-motor paralysis. Ophthalmoscopic examination by Dr. Leroy Pope Walker, shows that the temporal half of each optic nerve is very pale and the nutrient vessels diminished. This condition is considered to be fairly attributable to the child's evident anæmia. Choreic like twitchings are not present now, but the history shows that they existed in an earlier stage of case, and more than one physician has treated the child for chorea. Her facial expression is anxious, rather than vacant. She does not have the attacks of impulsive laughter often noticed in this disease. She suffers from palpitation of the heart on walking, but has no valvular lesion. Anæmic bruit is present in vessels of neck. Her headache is distinctly frontal. She does not feel dizzy in walking, but is unable to co-ordinate her movements. Sensibility of the skin to touch, heat and cold, and pain is found to be unimpaired, although not exhaustively tested. Special senses not affected. Child is bright and intelligent, and not irascible. Her sense of the posture of limbs is good.

The clinical assistant who first saw the case at the hospital considered it to be locomotor ataxia without Argyll-Robertson pupil, a not impossible combination. The writer changed the diagnosis to that of cerebellar tumor without increased knee-jerk, which is also a possibility. But the ophthalmoscope showing absence of optic neuritis or of post-neuritic atrophy, a more careful review of the case was made and the correct diagnosis arrived at.

The pathological anatomy and prognosis are so fully treated in the articles of Ladame and Bramwell as to render unnecessary any mention in this communication. The treatment is the same as that of locomotor ataxia. Suspension has been tried in some of the recorded cases without any benefit. Lena, an Italian writer, has reported[1] two cases treated by injections of organic nervous extracts after the method of Dr. C. Paul.

Non hereditary cases may occur with more frequency than is usually supposed. The "Index Medicus" for 1893 gives sixteen references to twenty three cases of Friedreich's disease, of which four were isolated cases, no other member of the family being affected. Thus Destree[2] records a case, aged twenty-one, brothers and sisters healthy, father an alcoholic, died of consumption, one paternal uncle epileptic. Senator[3] had a case in one of five sisters.

McCaw[4] publishes a case in which the hereditary history broke down at every turn. Strong history of tubercle in this family Chauffard[5] presents an isolated case which began at the remarkably early age of three and one half years.

To these can now be added Mackenzie's case and the writer's. It would seem to be desirable that other non-hereditary cases should be reported, in order to eradicate the fixed idea that Friedreich's ataxia is necessarily a family disease. The lesion in Friedreich's disease is a combined sclerosis of certain tracts in the posterior and lateral columns of the cord, together with the vesicular columns of Clarke in the gray matter, and the posterior roots. The entire cord is also congenitally smaller than the normal. The diseases with which it is likely to be confounded are locomotor ataxia, insular sclerosis, ataxic paraplegia, chorea, and cerebellar tumor. The differential diagnosis is clearly given in the article by Bramwell previously alluded to.

It has been suggested by one writer[6] that lateral curvature of the spine may give rise by pressure to cord symptoms, but a study of the case cited will show many and marked differences in its symptomatology from that of Friedreich's ataxia. Orthopedists generally do not accept the conclusions therein advanced, but agree with Bradford and Lovett that lateral curvature never gives rise to cord symptoms.[7] Although the author predicted that literature would soon teem with cases similar to his, the ensuing two years have not brought to light the expected inundation.

INCONTINENCE OF URINE AND FÆCES, CURED BY CIRCUMCISION.

By H. L. ROSENBERRY, M.D.,

MENOMINEE, MICH.

I WISH to report a case that has been very instructive to me. In September, 1893, I was called to see a child with incontinence of urine and fæces. The child seemed to be as healthful as the average four-year old, and aside from this difficulty had never taken any medicine. In making an examination I discovered what had apparantly been overlooked by the former medical attendants, an elongated prepuce. I said to the parents that the child should be circumcised without delay, as that might account for the dribbling of the urine, but supposed there was entire absence of the sphincter ani.

On the following day the child was anæsthetized and the circumcision performed. It healed nicely. At the time of the operation a digital examination revealed a patulous anus with no sign of a sphincter muscle. Supposing it to be absent I, of course, thought there would be no help for the incontinence of the fæces. When complete healing had taken place the bowel trouble entirely subsided, but he still had trouble with the retention of urine. I tried various remedies, and finally used the atropia ($\frac{1}{100}$ Wyeth's hypodermic) tablets, with instruction to cease when dryness of the throat appeared. The child is more robust than before and has fully recovered.

I am at loss to explain the process, but simply relate it as a fact. Will your readers cite to me similar cases if they know of such?

AN UNUSUAL ACCIDENT TO THE RESPIRATORY TRACT.

By M. D. BRIGGS, M.D.,

CHAMPLAIN, N. Y.

ON the evening of January 25, 1894, Ernest L——, aged seven, was brought to my office by his parents with the following history: About one hour previously, namely about 6 P.M., while chewing a mouthful of dried peas with which he had been playing, he had a little grievance and commenced crying. In the midst of his sobbing he sucked some of the partially chewed peas into his windpipe, and at once began to choke and strangle. His father immediately seized him and used such measures as he was able for his relief, such as clearing out the mouth and throat, inverting the child, and thumping his back. He recovered his breath, after which an emetic was given and the child brought with all haste to my office, something over two miles.

On examination I found him breathing easily and quietly, but the stethoscope revealed plainly the fact that some of the material had entered the respiratory tract. The laryngoscope was unsatisfactory, as the attempt to use it brought on a severe attack of dyspnœa, which subsided after a moment or two. Realizing the gravity of the case, I advised taking the child by first train to Montreal, as it could be easily reached in two or three hours, hoping that something there might be done to save him. They decided to take my advice and left my office, while I prepared to accompany them. In about five minutes a messenger came for me in great haste from a neighboring store where they had stopped to make a purchase.

I found the boy in a state of complete apnœa, cyanosed, pulseless, and apparently dead. Finding the heart still beating I immediately laid him on the counter, in a position to do a quick tracheotomy. I had bared the throat, found my landmarks, and in another instant would have made the incision, when there came a slight gasp. After a few seconds another came, and I laid down my knife. In a few minutes he was breathing fairly well, but lay in a semi-conscious condition. There was no further thought of Montreal, nor even of taking him home. A room was secured at the nearest hotel and he was removed thither. Another severe attack of suffocation came on as soon as we reached the hotel, in which the boy went through another terrible death struggle, and lay apparently dead on the bed, only to again revive for a repetition of the dreadful ordeal, for these attacks of laryngeal spasm occurred again and again.

Dr. J. M. Hackett and Dr. L. C. Dodge were called in consultation. All concurred in an almost hopeless prognosis. Tracheotomy seemed a forlorn hope, and was considered only as a measure for the relief of the laryngismus. The parents desired anything that would promise even a measure of relief. So I did a tracheotomy with careful attention to details. There was no more spasm of the glottis, but the operation gave no relief to the dyspnœa and cyanosis, which steadily increased. Sharp hissing sounds could be heard through the tracheotomy tube coming up from below. Death took place about twenty-one hours from the time of the accidental entrance of the partially masticated peas into the respiratory tract. An autopsy could not be obtained.

A FAMILY HISTORY OF DIABETES.

By GEORGE A. PHILLIPS, M.D.,

ELLSWORTH, ME.

A BOY eight years of age was seen by me in January of this year, with well-marked symptoms of diabetes mellitus, excessive thirst, emaciation, urinating four to six quarts daily, specific gravity of urine 1.046, with sugar in considerable quantities. The interest of the case lies in the fact that three brothers of his mother died of the same disease, their ages respectively three, eight, and seventeen, the diagnosis almost established by the history obtained by a member of the family was confirmed by communications from Dr. Thomas, of Brewer, Me., and Dr. F. O. Perry, of Orland, Me., the physicians who attended the children who died. The mother of the child whose history is given above, and a sister to those who died, has occasional symptoms of the same disease. There were five children, three dying of diabetes, one of typhoid fever, and the mother of child referred to.

HAVE THE RED BLOOD CORPUSCLES AMŒBOID MOVEMENT.

By WILLIAM MOSER, M.D.,

PATHOLOGIST TO ST. CATHARINE'S HOSPITAL, BROOKLYN.

IT is generally supposed that the red blood corpuscle is a "fixed" cell, *i.e.*, a cell not capable of amœboid motion like the white blood corpuscle. My observations are not in accord with this general belief. It is true that the red blood corpuscle, when obtained fresh (by pricking the finger-tip) and examined under the microscope, will not exhibit any property of amœboid movement, much less would it do this if the blood was heated and stained. The blood corpuscles when examined fresh rapidly become dehydrated, a dark ring soon forms on their outer border, looking like a membrane, many of them become shrivelled, "cremated," the cell soon dies. But in certain media like the urine they retain their vitality and certain fundamental differences can be noted. In over one hundred specimens of nephritic urine, containing blood-cells, I was positive that in every instance I could detect in most of the red blood-cells movement. In some cells I could see how the cell would retract in certain places, some becoming semilunar in shape, others could be seen taking on various shapes, reminding one of the condition known as "poikilocytosis" seen so frequently in progressive pernicious anæmia. Again the ordinary round shape would become long and narrow, and by waiting a few seconds it would again regain its rounded outline. All this could be seen and demonstrated in urine containing many blood cells. In short, it behooves us to examine the red blood corpuscle in the urine more closely.

158 ROSS STREET, BROOKLYN.

Progress of Medical Science.

Bacteria in Human Milk.—Dr. Ringel contributes the report of a series of investigations upon the bacteria found in human milk. Various observers had reported having found the staphylococcus aureus and albus, as well as the streptococcus, both in healthy milk and in that from mothers suffering from puerperal fever. Escherich examined 25 women. Of these, 24 specimens were sterile and 1 contained bacilli. He again examined 13 with puerperal fever, and found staphylococcus in 12; 4 being of the white and yellow variety intermixed; 8 the white only, and 1 of an uncertain form. Cohn and Neumann experimented on 43 cases of milk from healthy women, and found 36 containing staphylococcus albus, 1 staphylococcus aureus and pyogenes, 3 staphylococcus pyogenes albus and streptococcus pyogenes; in 2 all the above forms were united. The writer made a series of investigations, drawing and using milk from the deeper parts of the breast only, the experiments being made under the strictest antiseptic precautions. The milk was taken from 12 healthy and 13 unhealthy patients. The results were as follows: 3 specimens were sterile; 17 specimens contained staphylococcus pyogenes albus; 2 specimens contained staphylococcus pyogenes aureus; 1 specimen contained staphylococcus pyogenes albus and aureus; 2 specimens contained staphylococcus pyogenes albus and streptococcus pyogenes. An examination of the mouths of nursing infants revealed corresponding bacteria in their secretions.—*The American Journal of the Medical Sciences.*

A New Method of Using Cocaine for Local Anæsthesia.—Krogius (*Centralbl. f. Chir.*, No. 11, 1894) describes a new method of producing cocaine analgesia, which is based on the fact that, when a solution of this agent is injected into the subcutaneous tissue near to a nerve-trunk, it causes loss of sensation over a large zone corresponding to the peripheral distribution of this nerve. In order to reach the selected nerve-trunk with certainty, and to apply the cocaine to several of its branches at the same time, the author, in injecting the subcutaneous tissue, passes his needle across the long axis of the limb, and as the needle is thrust along, the solution is gradually discharged. An injection made in this way across the root of a finger will, in the course of ten minutes, result in analgesia of the whole digit, not of the skin only, but also of the tendons, the periosteum, and all the deep structures. If one or two injections be made transversely near the wrist, a considerable extent of the palm of the hand may be thus rendered analgesic. The sensibility of the ulnar side of the hand as far as the roots of the last two fingers may, it is stated, be abolished by injecting a solution of cocaine over the ulnar nerve at the back of the elbow. By injecting over both supra-orbital notches, analgesia may be produced in the whole of the middle portion of the forehead. The analgesia caused by this method of using cocaine attains its greatest intensity and extent from five to ten minutes after the injection, and is maintained for a quarter of an hour or even longer. The author injects only a weak (two per cent.) solution of cocaine, and keeps the patient recumbent for at least a quarter of an hour after the operation. This method has been practised with success at Helsingfors, in two hundred minor operations, such as amputation of the fingers and toes, excision of palmar fascia, and phimosis.

Compression of the Umbilical Cord During Delivery by Forceps.—Dr. Swayne has recently again directed attention to the danger to which the child is exposed during delivery by forceps, from pressure of the extremities of the blades on the umbilical cord, should it be so situated as to be compressed when the forceps has been applied (*The Lancet*). In a former communication on the subject Dr. Swayne instanced 153 cases of forceps delivery. In 23 of these the child was either born dead, or died soon after delivery; in 4 out of these 23 cases he attributed the death to compression of the cord by the forceps—that is to say, that this injurious compression had been noticed in the proportion of once in 38 cases. Since the time when this series of cases was published, Dr. Swayne has had 71 forceps cases, with 10 deaths of infants, and among these 10 stillbirths there were 2 cases in which the child's death was due to pressure of the forceps on the cord. In this second series, then, the accident in question occurred once in 35 cases—not very different from the frequency noted in the preceding series. Spiegelberg's estimate of the fœtal mortality in forceps cases is seventeen per cent. It certainly seems to be the fact, as Dr. Swayne says, that this particular danger—that is to say, compression of the umbilical cord by the forceps—has not received perhaps so much attention as it deserves. Dr. Swayne still agrees with a passage which he quotes from a paper by Dr. Galabin, published in 1877, namely, "that it has not been shown that the majority, or any considerable proportion, of the stillbirths which now occur in Britain would be preventable by a more timely resort to forceps."

Skin-grafting for Keloid.—Broca recently excised from the back of the hand and thumb an extensive keloid following a burn. The growth was half a centimetre in thickness, and held the hand at a right angle to the forearm. A flap from the abdomen was then grafted upon the hand and its pedicle severed in thirteen days after the operation. There were no drawbacks of any kind, and complete motion in the hand and wrist was restored.

Ingrowing Hairs.—Dr. Guthrie calls attention to a condition of ingrowing hairs, which presents itself in the form of bluish-white pimples, varying in size from a pin's head to a small pea, situated usually about the chin where the beard grows the thickest. Careful inspection of the unshaved chin and cheeks will show here and there the presence of "giant hairs." These are dark in color, and as thick as hog's bristles. The slightest traction with forceps suffices to painlessly remove them. The thickening is due to the deposit of a dark, soft material, which envelops the hair throughout its extent. This layer can be scraped off, and is soluble in liquor potassæ. The hair itself is also thickened, and its structure is blurred and indistinct. It is probable that the little bluish-white pimples form by the growing within the hair-follicle of what remains of a broken, thickened, and brittle hair. The condition occurs most commonly on a bearded face, but it is sometimes observed in other situations, as the axilla, the pubes, the periphery of the hairy scalp. Under the latter circumstances the condition is dependent rather on a blockage of the orifice of the hair-follicle than upon disease of the hair itself. Sometimes, instead of a single hair, such a follicle will contain a minute ring-shaped tress, composed of a dozen or more fine hairs. These are particularly common about the under surface of the penis, where they often suppurate and discharge a foul smelling mixture of pus and decayed sebaceous matter. In treatment giant hairs should be removed by means of forceps, but it is essential that no force be used. When the little nodules have formed, the overlying surface should be sterilized and an incision made with a sharp tenotomy knife. A portion of hair will present, and can easily be extracted.—*Medical News.*

A Canadian View of Russia—The *Canadian Medical Record* regrets that the next International Medical Congress will be held in Russia, "as we fear very few will trust their lives in that barbarous country," and thinks that "Vienna or even Montreal would be a much more acceptable and more accessible place." Montreal might be more accessible to the inhabitants of the North American Continent, but we assure our esteemed contemporary that Russia is not such a dreadful place. Many of its inhabitants go clothed and eat with forks, and the nihilists seldom kill more than sixteen visiting doctors in a week.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 11, 1894.

TOTAL EXTIRPATION OF THE UTERUS IN DISEASE OF THE ADNEXA.

THE importance which this subject has assumed of late is shown by the prominence assigned to it in Society discussions, notably that held before the American Gynecological Society at its recent meeting. The general practitioner who is not familiar with the rapid advances in gynecological surgery is apt to be somewhat appalled by the confident assertion that the uterus should be extirpated in all cases in which the adnexa are removed, on the ground that the organ itself, being diseased at the same time, is not only useless, but remains as a constant source of discomfort, and even of danger, to the patient. This, in a word, represents the dictum of the most advanced school, which as yet has but few followers among us. A further argument, which appeals strongly to abdominal surgeons, is that by removal of the uterus in cases of extensive suppurative disease of the adnexa, perfect drainage is secured per vaginam—the method which is now recognized as the ideal one—as was foreshadowed by Sims a quarter of a century ago. To this the more conservative reply that securing vaginal drainage by hysterectomy is too heroic a procedure, since the same result can be obtained by retaining the uterus and draining through Douglas's pouch.

As is usually the case when a novel and radical surgical operation is first advocated, the adherents of hysterectomy and its opponents see only their side of the question. Reading the enthusiastic statements of the former, the occasional operator would infer that nothing was easier and safer than the extirpation of the uterus after removal of the diseased adnexa—in fact, that it was comparable with a simple ovariotomy. But it must be remembered that the few surgeons who report such remarkably favorable statistics are unusually skilful operators, who have acquired their special aptitude by a wide experience in hystero-myomectomy. An operation which is easy for them is formidable to one of limited experience in this work. Therein lies the danger to the rank and file of cœliotomists, whose name is legion.

The technique of the operation is the main difficulty in the way of the unqualified acceptance of the proposition that a uterus without its tubes and ovaries, and especially a diseased uterus, becomes a useless appendage, and should therefore be extirpated. No reasonable gynecologist can deny that the uterus is frequently a source of trouble, that it may be the cause of persistent pain and hemorrhages, and be open to repeated infection (gonorrhœal or septic) months, and even years, after the removal of the diseased adnexa. Hence, even the most conservative acknowledge that there are cases in which it must be admitted that it would have been better if the organ had been removed at the time of the operation. But is hysterectomy under these conditions to be recommended to the profession at large? To this we reply unhesitatingly in the negative. Given a case of double pyosalpinx with firm intra-pelvic and intestinal adhesions in which considerable manipulation has been necessary, we affirm that many patients are not in a condition to bear the extra amount of shock involved in removal of the uterus. In spite of the advantages afforded by Trendelenburg's posture, there are few surgeons who can complete the additional operation in "twenty minutes," as is claimed by its advocates. So far as our observation goes, twice that time is required. We have yet to see a case in which a difficult salpingo-oöphorectomy was supplemented by extirpating the uterus, when the shock was not most marked, and the convalescence, when recovery followed, protracted.

This point was emphasized by Dr. Coe in reporting a recent case to the New York Obstetrical Society, and was dwelt upon by Dr. Bache Emmet in the discussion before alluded to. The latter gentleman also raised the pertinent question whether a patient in private practice would consent to such a radical mutilating operation for disease of the adnexa, if she were consulted beforehand. To perform such an operation without her full knowledge and co-operation would be assuming a responsibility which few would care to take, even in this radical age. We doubt if the average woman would be sufficiently influenced by the arguments which appeal so strongly to the abdominal surgeon, as to take the additional risks involved in total extirpation.

THE STATUS OF CHRISTIAN SCIENCE IN NEBRASKA.

A CHRISTIAN scientist in Nebraska was recently tried before the District Court of Gage County, Neb., on the charge of practising medicine contrary to the statutes of that State. He was acquitted by the jury, but the prosecuting attorney carried his exceptions to the Supreme Court, where they were sustained. Judge Ryan handed down a decision in which he said that the fact to establish a State Board of Health, to regulate the practice of medicine in Nebraska, is as much directed against any unauthorized person who shall profess to treat any physical or mental ailment of another, as against one who practises medicine as the term is generally understood.

The section of the act upon which this decision was based reads as follows: "Any person shall be regarded as practising medicine, within the meaning of this act, who shall operate on, profess to heal, or prescribe for, or otherwise treat any physical or mental ailment of another. But nothing in this act shall be construed to prohibit gratuitous services in case of an emergency, and this act shall not apply to commissioned surgeons in the United States army and navy, nor to nurses in their legitimate occupations, nor to the administration of ordinary household remedies."

This law is certainly rigid, but not too much so, and

any suffering that might arise from a too strict application of it is prevented by the emergency clause. It would be impossible for a layman to be punished for saving life in the absence of a physician, as has actually occurred in France.

THE EYE AND SURGICAL TREATMENT OF EPILEPSY.

There has been beyond any doubt a factitious prominence given to the treatment of epilepsy and other nervous disorders by surgical treatment of the eye muscles. It is the general opinion of neurologists that there is little or nothing to be gained by it, while, on the other hand, much harm may be done.

Dr. Casey A. Wood, of Chicago, has recently (*New York Medical Journal*) gone over the subject very thoroughly, and has called attention to the numerous cases of epilepsy on record which have been cured by minor surgical operations of various kinds. His conclusions are worth presenting here: He says.

"1. Heterophoria in some form, latent or manifest, can be shown to exist as an ocular condition in fully ninety-five per cent. of all individuals.

"2. Alone and when associated with ametropia it is not an uncommon cause of so-called asthenopia.

"3. In the latter case the correction of the accompanying refractive error in the large majority of cases relieves all the symptoms set up, both by the ametropia and muscular anomaly; when it does not, the heterophoria may be said to be responsible for the asthenopia.

"4. It is highly probable that when epilepsy is in part or wholly the result of eye-strain other evidence of the latter is present.

"5. It must follow from the foregoing that in the eye treatment of epilepsy of any decided degree the correction of the ametropia, and not the correction of the heterophoria, is the first and most urgent duty of the ophthalmologist, and that in cases where both are corrected at the same time it is fair to suppose that the results, if any, are due to the ametropic correction.

"6. In cases of epilepsy with heterophoria and emmetropia, or where the correction of refractive errors has failed to relieve the asthenopic symptoms and the production of orthophoria is followed by cure of the epilepsy and the asthenopia, it is just to say that the operation on the eye muscles or treatment of them has produced the effect of stopping the convulsions.

"7. In the absence of ocular symptoms, apart from the epilepsy, an operation upon the eye muscles stands in the same therapeutic relation to a cure or relief of the disease as do other surgical procedures that have during the past century been in vogue, such as tracheotomy, setons, ligature of the vertebral arteries, trephining, oöphorectomy, circumcision, castration, the actual cautery, the resection of stray scars, and so on.

"8. These operations bring about a cure or relief of the epilepsy (both idiopathic and hystero-epilepsy) by their powerful mental effect upon the patient—a truth long recognized by neurologists.

"9. Genuine cures of epilepsy by eye treatment of any kind must necessarily be confined to those cases where a faulty ocular apparatus acts as a peripheral irritant. It remains yet to be shown that anomalies of the extrinsic muscular portion of that apparatus are to any large extent responsible for the seizures of epilepsy.

"10. The eye treatment of epileptics who present signs of ocular distress has not received that attention which the importance of eye-strain in the category of reflex irritants seems to call for. The eyes should be carefully examined in every case of epilepsy where asthenopic symptoms are present or are suspected.

"11. I question the wisdom of encouraging the profession, and through them the laity, to believe that every case of idiopathic epilepsy is a suitable one for eye treatment, but prefer to say that only those cases are fit subjects, in the proper scientific sense, for eye treatment whose visual organs are palpably the source of irritation, giving rise to symptoms generally included under the term eye-strain.

"12. That when all remedies fail, some such operation as Reynolds suggests—easy to perform, perfectly safe, and yet of a severity and character tending to make a lasting impression on the patient's mind—is indicated. I would suggest the removal, at intervals, of small pieces of skin from various parts of the body, the denuded spots being allowed to heal by granulation."

APPARENT DEATH BY ELECTRICITY.

At a recent meeting of the Biological Society of Paris, Dr. d'Arsonval reported the case of a workman who was caught between two cables conveying electricity from the station of La Chapelle to that of Epinay-sur-Seine. The current measured 5,000 volts, and the man received the full discharge for a period of five minutes which elapsed before the current was shut off. It was not known at first what caused the disturbances noted in the current, and the man was not discovered until forty minutes later. He was then apparently dead, but attempts were made to resuscitate him by artificial respiration after Sylvester's method. These failing, resort was had to rhythmical tractions of the tongue. Respiration was in this way gradually re established and the man made a quick recovery, being none the worse for his experience except that he suffered from the burns. The reporter believed that death from electricity is not immediate, but follows asphyxia and syncope, conditions which may often be removed by treatment. If this is so, may the criminals executed in this State be said to be killed by electricity or during the autopsy?

Reformatories and Jails.—An exchange says that there are 1,758 county jails and but 44 juvenile reformatories in the United States. In Great Britain there are over 400 reformatories and industrial schools for juvenile delinquents, and the number of prisons has been reduced from 113 to 57 within the past ten years.

The Oldest Man in the World.—A Frenchman now living in Russia is said to have attained the immense age of one hundred and twenty six years. From a very interesting account of his life, just published in a Russian journal, it appears that he was born in Paris on April 17, 1768. He has a vivid recollection of the "Terror." He joined Napoleon's army in 1798. He fought in the battles of Austerlitz and Jena, shared in the campaigns of Egypt and Spain, and finally was one of the four hundred thousand men who followed Napoleon to Moscow.

News of the Week.

The Cholera Epidemic in Europe shows no signs of abating as yet. The disease is raging in many provinces of Russia and in Galicia, and lurks obstinately along the shores of certain streams in France, Belgium, and Holland. In St. Petersburg there were 313 new cases and 240 deaths reported for the week ending August 4th, and in the city and province of Warsaw during the week previous the new cases numbered 553 and the deaths 296. In sixteen infected districts in Galicia there were 126 new cases and 83 deaths on August 5th and 6th. In many towns in this province all industry and commerce are at a complete standstill; the rich have fled and the poor are left in a starving condition. In Holland the disease is present in Amsterdam, Haarlem, Halfweg, Dordrecht, and Maastricht, 26 new cases and 13 deaths having been reported in these places on August 1st. Deaths from cholera have also taken place in Dantzic and other towns in Eastern Prussia. The North German Lloyd and Hamburg American Steamship Companies are about to erect buildings at Illowo and other places on the Russo German frontier for the detention and examination of intending steerage passengers to this country. The stations will contain disinfecting apparatus for baggage and clothing, and bathing-places for the emigrants.

Openings for the Unemployed. — The war between Japan and China promises to be a protracted one, and it is probable that the services of foreign surgeons will be in demaud in the Japanese army and navy, if not in the Chinese also. Yet we would not advise young surgeons to go to the expense of a trip to Japan without having some definite assurance that their services will be wanted. And furthermore, a law was passed in 1860 making it a penal offence for citizens of the United States to take part in a war against a friendly nation. That probably, however, would not apply to the case of non-combatants such as surgeons and nurses.

The Plague is still epidemic in Canton in virulent form, the mortality being ninety per cent. of those attacked. For the three months ending July 1st it is estimated that forty thousand deaths have occurred. Cholera has also made its appearance there in epidemic form.

The British Medical Association.—A number of Americans were announced to be present at the meeting of the British Medical Association in Bristol last week. Among them were Drs. J. J. Chisholm, G. M. Gould, J. L. Thompson, G. T. Stevens, Henry D. Chapin, W. P. Northrup, and Dillon Brown. Dr. Northrup, in addition to several communications of his own, read a paper on intubation for Dr. Joseph O'Dwyer, who was unable to accept the invitation to be present in person.

The French Society of Dermatology and Syphilography held its fifth annual meeting at Lyons on August 2d and two following days.

Dr. William J. Little, of London, "the father of English Orthopedy," died on Saturday, July 7th, in the eighty-fourth year of his age. He was for many years physician to the London Hospital and lecturer on the Practice of Medicine in the college. His first work, "A Treatise on Club foot and Analogous Distortions," was published in 1839, and his last, on "In-Knee," written jointly with his son, Mr. E. Muirhead Little, in 1882. Soon after that he retired from practice to pass the remainder of his days at his country residence.

Dr. Judson B. Andrews, Superintendent of the Buffalo State Hospital for the Insane, died in Buffalo, August 3d, aged sixty years. He was a graduate of Yale College in the class of 1855, and received his medical degree in 1863. During the War of the Rebellion he served as a captain in the Seventy-seventh New York Infantry, which was organized at Saratoga, but resigned July 16, 1862. He is also credited with service as a surgeon in a Connecticut regiment, but his name does not appear in the New England roster of volunteer officers. He was ex-President of the Erie County Medical Society, a founder and ex-President of the New York State Medical Association, as well as ex President of the Psychological Section of the Ninth International Medical Congress. In 1892 he was elected President of the American Medico-Psychological Association. His many years' service as Assistant Superintendent of the Utica Asylum, as Superintendent of the Buffalo Asylum since it was opened in 1880, and as the working editor of the *American Journal of Insanity*, well qualified him as an expert in his chosen department, to which, indeed, he contributed many enlightened reforms.

The First French Congress of Internal Medicine will be held in Lyons, under the presidency of Professor Gailleton, mayor of the city, during the week beginning on Thursday, October 25th. Medical men of any nationality may take part in the proceedings on payment of a subscription of twenty francs, but all communications must be in the French language.

The Medical Publishers' Association meets at Hot Springs, Va., August 13th and 14th.

The American Journal of Insanity will hereafter be published in Chicago, under the managing editorship of Dr. Richard Dewey. The Journal has become the organ of the American Medico-Psychological Association, but its general form and scope will remain unchanged.

Insanity and Crime.—At the meeting of the British Medical Association, just held at Bristol, a discussion on "The Law in Relation to the Criminal Responsibility of the Insane" took place before the Section on Psychology. It was opened by Dr. L. A. Weatherly, who advocated a change in the English law on this subject. At present the law is that if the accused was conscious that the act was one which he ought not to do, and if the act was contrary to law, he is punishable. Dr. Weatherly maintained that if it is proved that the accused is certifiably insane, and further, that the crime charged is the outcome of his mental disease, he is entitled to a verdict of insanity and should be placed under treatment in an asylum for the insane and not be punished as a criminal.

The Sabathu Leper Asylum.—The annual report of this asylum for 1893 has been received. The superintendent acknowledges with gratitude a ready response to his appeal for increased donations, but says that the need for help is still urgent. Several contributions were received from friends in the United States. For the benefit of those interested in the study of leprosy some excellent photographs have been taken of a group of

the leper inmates, and are sold for the benefit of the asylum at one dollar per copy, including postage, and a short history of each person. The address of the superintendent is Dr. M. B. Carleton, Sabathu, North India.

Pregnancy at an Advanced Age.—In the Berlin *Intelligenzblatt* of July 5th, among the death notices was one of Frau Marchoun, sixty-eight years of age, the cause of whose death was said to be puerperal fever.

A Monument to Volkmann.—At the recent bicentenary celebration of the University of Halle, a monument to Professor Richard v. Volkmann was unveiled with appropriate ceremonies.

A Medical Monk. — Dom Sauton, a Benedictine monk, and a doctor of medicine as well, who recently returned to Paris from a mission, both religious and scientific, to the lepers of the Scandinavian Peninsula, has started again on an extended tour among the lepers of Asia Minor and Greece, and will visit Japan and the Sandwich Islands before returning to France.

Dr. Charles S. Briggs succeeds his father, the late Dr. W. T. Briggs, as Professor of Surgery in the University of Nashville.

The St. Louis "Clinique."—Dr. Emory Lanphear has assumed the editorial management of the above-named journal.

Sterilization of Doctors.—It has been proposed by Gutmann that stations be erected in convenient localities in cities and large towns where physicians may go to be thoroughly disinfected immediately after they have visited a case of infectious disease, and before paying any further visits. The operation will take about fifteen minutes, and then the doctor may go about his business, proud in the consciousness of being clean and no longer a menace to the health of his fellows.

The Iowa Public Hall Association, whose aim, as announced in the notice of meeting, is purely philanthropic, will hold its fourth annual session in Des Moines, September 6 and 7, 1894. Membership in the Association is not limited to medical men, but all interested in the prevention of sickness are eligible.

The American Electro-Therapeutic Association will hold its fourth annual meeting at the Academy of Medicine, in this city, on September 25, 26, and 27, 1894. An interesting programme is announced. The President of the Association is Dr. W. J. Herdman, of Ann Arbor, and the Secretary, Dr. Margaret A. Cleaves, of New York.

Diphtheria Germs in Cheese.—The Board of Health in this city recently received a telegram from the Secretary of the State Board of Health, stating that some cheese which had been shipped to a firm of provision-dealers contained Loeffler's diphtheria bacilli, and requesting that samples be submitted to the bacteriologist of the Department for examination. This was done, with the result of proving that the suspicions of the State Board were well founded. The shipment consisted of three thousand pounds, and the entire lot has been seized and destroyed. There was diphtheria in the family of the farmer from whom the milk was obtained. The tests thus far made have been culture-tests, but inoculation experiments are to be made on guinea pigs.

Mr. Gladstone's Eyes are now reported to be so much improved that he is able to dispense with goggles.

Thyroid Extract has lately been recommended in the treatment of obesity. But it is well to remember that this is a dangerous substance, often causing great weakness of the heart, and it should be used with caution.

An International Congress for the Protection of Infancy will be held in Bordeaux, commencing July 22, 1895. The work of the Congress will be divided into three sections: 1, Physical protection, in which questions of day nurseries, infant and foundling asylums, etc., will be discussed; 2, moral protection, in which will be considered orphan asylums, country homes, the rescuing of abandoned children, etc., and 3, administrative protection, in which the various laws, existent and proposed, relating to the care of young children will be discussed.

Dr. Hans Buchner has been appointed Professor of Hygiene and Director of the Hygienic Institute in Munich, to succeed Professor von Pettenkofer.

A Royal Doctor.—*The Lancet*, with inconceivable temerity, makes the awful suggestion that the infant son of the Duke of York be educated as a physician or surgeon. It might not be a bad thing for the young man to be provided with a livelihood in case anything should happen to interfere with the exercise of his hereditary profession. Edward Albert Christian George Andrew Patrick David Wettin, M.D. Lond., F.R.C.P. Edin., F.R.C.S.I., Defender of the Faith, etc., etc., would be quite imposing.

The American Public Health Association will hold its twenty-second annual meeting in Montreal, on September 25–28, 1894.

Students in Leipsic.—The University of Leipsic is disturbed by the gradual decline in the number of its students. Twenty years ago it stood at the head of German universities, while to day it has a thousand less than Munich, and twice that number less than Berlin. Those that remain are studiously inclined, however, for they recently held a meeting in which a resolution was passed to abstain from beer drinking in the forenoon, on the ground that early beer interfered with honest work.

The Earning Value of an Eye Mathematically Appraised.—The earning value of an eye depends on various conditions; it is evidently greater if the remaining eye has poor sight than if the remaining eye has good sight; for in the first case its loss would practically be equal to the loss of both eyes. Professor Zehander has furnished us with a formula by which the earning capacity of the remaining eye (and consequently the earning value of the lost eye) can be appraised for the manifold conditions of sight. The normal sight of an eye being valued at 100, the earning capacity of the remaining eye is $\frac{2+10}{3}\frac{0+0}{0} = 66\frac{2}{3}$ per cent., hence the loss of one eye amounts to $33\frac{1}{3}$ per cent. of the former earning capacity, provided both eyes had full vision. But suppose the vision of the remaining eye is only four-fifths, its earning capacity would be $\frac{2+8}{3}\frac{0+0}{0} = 53\frac{1}{3}$; hence the lost eye would have an earning value of $46\frac{2}{3}$ per cent., and thus the loss in earning capacity can be estimated under all conditions if in the above formula the degree of vision of the remaining eye is substituted for 100.—*Journal of the American Medical Association.*

Society Reports.

Congress of American Physicians and Surgeons.

Third Triennial Meeting, held in Washington, D. C., May 29, 30, 31, and June 1, 1894.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twentieth Annual Meeting, held at Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from page 90.)

THIRD DAY, FRIDAY, JUNE 1ST.

The Treatment of Convalescence and the After-care of the Insane.—DR. HENRY R STEDMAN, of Boston, considered the dangers attending convalescence in insanity and the precautions necessary to prevent relapse or prolong remissions. General rules and advice regarding the prevention of insanity are not regarded even by predisposed subjects, and are practically of but little use. The case is different when once an attack of insanity has been experienced. Although in certain cases the proper conduct of convalescence is vital to mental health, the study of this period is confined to a few scattered suggestions in the works on insanity. Instances of abrupt recovery, with almost no convalescent stage, are rare. Although it may happen in chronic cases, it occurs, as a rule, in those of short duration—notably confusional insanity and the toxic and neurotic insanities.

Lucid intervals or spurious convalescences differ often in no respect from genuine recovery, with the single and essential exception that the sleep does not improve or is worse. This is a valuable indication in the prognosis of permanent return to reason.

To the cardinal signs of convalescence should often be added the disappearance of decided fear of a return of the attack and dread of the stigma to follow. It is important to be informed regarding normal and usual physical troubles of the patient, as their reappearance is another and valuable indication of recovery; so, also, a knowledge of the sequence of immediate prodromata of an attack. They are often repeated in reverse order while the patient is getting well.

Complete mental rest during menstrual epochs, so highly important at this time, is often disregarded, and application of the mind, even to a slight degree, in study or other work, is equally to be deprecated.

Early discharge from the asylum, or from special care away from home, is to be advised against, as a rule, especially in cases of melancholia with a history of suicidal attempts and after acute mania, the most exhausting form of insanity, and one which leaves the patient particularly susceptible to slight influences for a long time.

On the other hand, we should frequently advise early removal in other cases convalescing from melancholia, particularly when homesickness is a marked feature and occasionally when there is refusal of food. Certain cases of mild mania, also paranoiacs who are independent in the asylum and actively oppose treatment, are steadied by outside life. A change also works well until its novelty has worn off.

The first year or so after recovery is a very critical time. The reader gave a number of indications in special cases and suggestions for prevention of relapse.

The above remarks applied chiefly to well-to do patients. An important branch of this subject is the means for the after-care of the pauper insane. There is practically no provision outside of asylums for this class, and practically little advice or other help is given these unfortunates on leaving asylums. While for the physically sick, on the other hand, there is abundant provision for their care during convalescence, and the discharged convict is greatly helped and encouraged by charitable societies for the purpose. Asylum physicians often hesitate to set certain patients at liberty whose mental condition seems to have so far improved as to make it useless to keep this class longer under care (and even some who have fully recovered), for fear that, thus suddenly thrown on their own resources, without oversight, or perhaps means of support, they will fall back into their old habits of life which gave rise to their insanity. This fact, and their delicate mental condition, often render them easy victims to designing people.

These and other reasons have led to the formation, in France, of protective societies, called "Societies of Patronage" under official auspices. Their duties are to aid convalescent or recovered pauper patients by gifts of money, clothing and tools, redemption of articles in pawn, payment of rent, admission to convalescent homes in cottages intermediate between confinement and complete freedom, or in hospitals or house of refuge, securing situations for them, and finally their supervision wherever employed. This work continues during the first month or two after the patient's discharge. Similar societies or means of relief have been adopted in England and Scotland. They were described in detail. There is no better work on the score of both humanity and public economy than the adoption in this country of similar means for the prevention of insanity.

DR. E. D. FISHER was of the opinion that patients left the asylum too early. In cases where they are oversensitive regarding their previous incarceration, something must be done to care for them and obviate a relapse. He was in favor of establishing convalescent homes for such patients, and spoke at length in confirmation of the views of the author of the paper.

DR. DERCUM thought this matter a very important phase in the care of the insane. It is, however, quite difficult to deal with individual cases. Where the element of exhaustion was a prominent causative factor, the patient required detention and care much longer.

DR. STARR was glad to know that Dr. Stedman favored the earlier removal from asylums of melancholics. One of the chief difficulties was in controlling the family, who did not know how to manage the patient after his return.

DR. JONES, of Minnesota, said that in Minnesota, since the word asylum had been changed to that of hospital, it had tended to remove any of the supposed stigma that has been usually attached to people who have been in institutions for the insane.

DR. KNAPP and the President concurred in the views expressed by the reader of the paper.

DR. DANA said that the subject was of great economic as well as medical importance; he would suggest that a committee be appointed to investigate the matter.

This suggestion was then presented in the form of a motion, which was carried. The President then appointed as a committee Drs. Stedman, Dana, and Dercum.

Exhibition of a Suicide's Brain with Two Pistol ball Wounds.—DR. BURT G. WILDER, of Ithaca, exhibited a specimen and showed a dozen photographs of various aspects and blackboard diagrams of the left side and of a transsection at the level of the fatal wound.

W. I. B., dentist, thirty-five years of age, of Ithaca, N. Y., on April 7, 1894, was found in his office, dead, a $\frac{32}{100}$ revolver clasped in his right hand. There were two bullet-holes—one in the middle of the forehead, the other in the right temple, neither ball having emerged. In accordance with his written directions, the brain was preserved in the museum of Cornell University as specimen 3,129.

The first ball, presumably deflected by the skull, passed caudo-ventrad to the cranial floor and was reflected dorso-caudad at nearly the same angle to a point just cephalad of the precommissure, where it lodged, having merely abraded the mesal surface of the left frontal lobe. The second ball entered at the right sub frontal gyre, passed obliquely sinistro-caudo dorsad, tore the callosum and intervening structures, and emerged in the second left central fissure. Since there was no suspicion of foul play, and documents in the deceased's handwriting declared

his intention to commit suicide, the case exemplifies the possibility of two self inflicted bullet-wounds of one brain.

The fissures present many peculiarities. The most perplexing is the apparent coexistence of two central fissures on each side. The only two such cases hitherto observed were recorded by Giacomini and Calori. Suicide had been committed by a grandfather and one uncle and attempted by another uncle.

Dr. Dercum had examined a large number of brains of the insane, but he had never seen such an instance as that presented by Dr. Wilder.

Dr. Dana said that he had no doubt that the anterior of the two fissures was the fissure of Rolando. The interruption of this fissure on one side by a bridging convolution was extremely rare and very interesting. The brain presented a unique fissuration. He could not understand how a primary fissure like the Rolandic could be doubled in any event, and was skeptical of the genuineness of reported cases.

Infantile Hemiplegia, Imbecility, and Epilepsy; Craniotomy; Marked Improvement.—Dr. Edw. B. Angell, of Rochester, reported a case and read a paper with the above title. The salient features of the case were forceps delivery, succeeded by double ptosis, occasional tonic spasm of right arm, contracture, and hemipalsy of right hand. Physical and mental development were slow, and epilepsy, with three to five seizures daily, supervened three months prior to the operation. At time of examination the child was partly imbecile. Skull measurement gave a cranial index of 77; palate was high-arched, teeth jagged, and right wrist and hand, much smaller than left, were helpless.

A diagnosis was made of pressure in neighborhood of the hand-centre of left motor area, due either to a hemorrhagic plaque or cyst. Craniotomy was decided upon, as a tentative measure, with a view of relieving pressure and consequent symptoms, while avoiding the greater risk of opening the dura necessary to removal of the cyst-wall. The operation was performed March 13th last, and, upon removal of the trephine button, a sub-dural hemorrhagic cyst was found. The cranium overlying the cyst had become very much thinned, and was freely cut away beyond the limits of the cyst. By an aspirating needle a half drachm of fluid was removed; otherwise the dura was not injured. The scalp incision healed readily; but, through an overtight bandage, œdema developed, and by the eighth day caused sufficient pressure to develop a hard convulsion and high temperature. With the remedying of this, marked improvement in all the symptoms ensued.

At the present time (three months after the operation) there has been no recurrence of the epileptic attacks, while there has been a commensurate improvement in the mental and moral condition.

Dr. Mills considered it presumable that the cyst which was not opened was a porencephalic cavity, and that opening and draining it would have been useless.

Dr. Putnam agreed with Dr. Mills. He said it was rarely possible to remove a cyst satisfactorily. In a case seen by him the cyst was tapped and the drain left in. Improvement followed.

Dr. W. A. Hammond spoke of two cases on whom craniotomy was performed. One was eighteen years of age, and became an imbecile as a result of an injury to the head. He remained in this condition four years. After operation there was improvement at the end of two months. At the end of a year the improvement was marked. In the other case, of a similar character, the operation was followed by improvement.

The President said cysts differed in character. The superficial cysts were due to meningeal hemorrhage during labor, and could be satisfactorily treated by operation.

Dr. Angell, in closing the discussion, said this was not a case of porencephalus, but an arachnoid cyst from a meningeal hemorrhage.

Infantile Amyotrophic Lateral Sclerosis of the Family Type.—Dr. Charles Henry Brown, of New York, gave the history and report of a case of this kind. The disease occurred in a boy fifteen years of age. There was marked emaciation, particularly in the upper part of the body, and paralysis and atrophy of all the facial muscles, excepting those of mastication. Fibrillary twitchings were present all over the body. The superficial and deep reflexes were active. Ankle clonus was demonstrable. There was double lateral curvature of the spine. Mentally the boy was fairly bright. He cries readily and is amused at trifles. Is microcephalic, and acts and appears like a child of ten. There are evidences of a general arrest of development. Dr. Brown considers his case as belonging to one of the family types of infantile progressive bulbar paralysis, plus the same implication that is found engrafted upon the progressive poliomyelitis of adults, and which gives us amyotrophic lateral sclerosis. In muscular myopathies the respiration is not involved. The upper facial muscles are usually unaffected, and the "taper mouth" is not observed. The atrophy is more irregular, more bilateral; that is, it is worse on one side. Electric reactions are not of especial importance in diagnosis. In some reported cases of infantile progressive bulbar paralysis they are normal; in others, degenerative.

To place this case among the scapulo-humeral or facio-scapulo humeral types of muscular atrophy is out of the question. Though the neck is much thinned, the scapulo humeral group and the back muscles are generally the best the patient has. What muscles he does possess are active, and the exaggeration of reflexes, the fibrillary twitchings, and the retractions of tendons that are present, though slight, preclude a peripheral origin of the disease. As far as is known, no case of the kind has ever been reported and diagnosticated as infantile amyotrophic lateral sclerosis of the family type. Hoffman's case, a boy aged eleven years, closely resembles it. Here, too, there was marked labio-glosso laryngeal paralysis, great emaciation of upper extremities of the trunk, extending down below the hips, together with exaggerated reflexes in the lower extremities and diminished reflexes in the upper. In Hoffman's case the atrophy was probably too extreme in the upper extremities to admit of much response. In all the cases reported of these bulbar diseases belonging to groups of family types there has been marked difficulty of respiration and special implication of the upper branch of the trifacial nerve.

Dr. Knapp showed a microscopic specimen from a case of amyotrophic lateral sclerosis which occurred in a man aged fifty years. The disease progressed very rapidly. He died at the end of fourteen months of broncho-pneumonia. There were no bulbar symptoms. The section presented showed marked vascularity in the sclerosed portions of the cord.

Dr. Putnam reported an analogous case of bulbar paralysis in a young child.

Dr. Preston, of Baltimore, had seen a child two years of age in whom spastic symptoms, such as exaggerated knee-jerk and ankle clonus, developed soon after an attack of acute poliomyelitis.

Ingravescent Cerebral Hemorrhage Treated by Ligation of the Common Carotid Artery.—Drs. F. X. Dercum and W. W. Keen, of Philadelphia, presented a joint paper with this title, reporting two cases. In the first case the symptoms pointed to a slowly progressive capsular hemorrhage, extending over three days before ligation of the common carotid was resorted to. The symptoms were steadily progressive and threatened a fatal termination. Ligation of the carotid, as proposed by Mr. Horsely, promptly arrested the symptoms, and the man made an excellent recovery. Months afterward merely symptoms of a spastic hemiplegia persisted, but they were not very marked.

The second case was one in which the symptoms pointed to a progressive hemorrhage occupying eight hours. The patient's condition was so grave at the time of the operation that little was hoped from it; and indeed it proved useless, patient dying several hours afterward.

Dr. Dercum pointed out that the class of cases in which benefit is to be hoped for from ligation of the common carotid are those in which the hemorrhage is decidedly ingravescent in type. He also dwelt upon the difficulties of a differential diagnosis between hemorrhage and thrombosis in such cases, and pointed out that even in case of an error in diagnosis it could not be said that the operation involved additional risk to the brain. Finally, he suggested that, instead of ligation of the vessel, the expedient of compression of the common carotid should be tried in every case of apoplexy as soon as the physician arrived. A surgeon is not always at hand, and besides compression of the carotid is so simple a procedure that a bystander can easily be instructed to apply it.

Dr. Frank Fry, of St. Louis, knew of several instances in which the operation had been done. All proved fatal. He believed that none of them were indicated or justifiable.

Dr. Knapp believed that the neurologist does not see the case until it is too late to make a satisfactory diagnosis.

The President thought the chief difficulty was in diagnosis, and that the hemorrhage was usually a self-limited one.

Dr. Dercum, in closing the discussion, said the operation was only indicated where the diagnosis of ingravescent apoplexy was definite.

Merycism.—Dr. W. A. Hammond, of Washington, defined this condition as the functions of rumination and remastication in the human subject. Only about fifty cases have been reported. Several cases were referred to, among them that of the distinguished physiologist, Brown Séquard, who had acquired it as a result of experiments performed upon himself. The case reported was that of a young man, whose mental condition was impaired and who was also the subject of merycism. No special treatment was undertaken against the merycism, but the patient was trephined with the purpose of improving his mental condition. There were no unusual features connected with the operation; but it was noticed that regurgitation did not occur with the meals he subsequently ate till on the fifth day, when there was a slight return. Eight days later a similar button was removed from the corresponding part of the left side of the skull. From that time (about six months ago) till the present there has been no regurgitation.

Whether the cure of the merycism in this case was directly due to the operations on the cranium or the result of the mental improvement is a question which it would be difficult to answer.

Dr. Knapp was unaware that so few cases had been reported in this country. Two cases had come under his notice. Both were physicians in good mental condition. He thought a distinction should be made between congenital and acquired merycism.

Dr. Lloyd believed that some cases should be considered as a neurosis allied to hysterical vomiting, such as regurgitation from the œsophagus.

The President had seen a man who had conquered the habit by the exercise of his own will. His views were in accord with those expressed by Dr. Lloyd.

Dr. Hammond said that acquired merycism was always due to overloading the œsophagus and to the bad habit of rapid eating. He thought it extremely doubtful as to its being a neurosis.

Chronic Chorea.—Dr. Lloyd, of Philadelphia, exhibited a large number of sections from the mid-brain, pons, medulla, and spinal cord of a case of chronic chorea.

Election of Members.—The following named gentlemen were elected to active membership: Dr. Ira Van Gieson, of New York; Dr. E. B. Lane, of Dorchester, Mass.; and Dr E. D. Bondurant, of Tuscaloosa, Ala.

Election of Officers.—The officers elected for the ensuing year were: *President*, Dr. Philip Coombes Knapp, of Boston; *Vice-Presidents*, Dr. F. X Dercum, of Philadelphia, and Dr. W. A. Jones, of Minneapolis; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Eleventh Annual Meeting, held in Washington, D. C., May 29, 30, 31, and June 1, 1894.

(Continued from page 124.)

Fourth Day, Friday, June 1st.

Rarity of Phthisis in the Highlands of Pennsylvania and New York.—Dr. Guy Hinsdale, of Philadelphia, read a paper with this title: He said that, if a physician were asked to name a district most free from phthisis in New England or the State of New York, he probably would name the Adirondacks. He wished to draw attention to a near-by region in Pennsylvania and New York, measuring 12,000 square miles, where the death rate from phthisis was as low as 1 in 1,091 persons living. He proceeded to describe the tier of counties plotted on a map, and said that as the maritime tier of counties was approached in New York there is an increasing death-rate. The region in Pennsylvania and New York under discussion had a population of sixty-two per square mile. It was largely an agricultural section. He claimed for it elevation and an equable temperature. The mountains were covered with vast areas of hemlock.

During May, June, July, August, and September, it offered an excellent climate. November to April, it was solid old-time winter weather. The area generally was broad, high table-land. Pneumonia and pleurisy are uncommon. The mountain-tops are above fog and moisture. In McKane County in 1880 there were 1,330 living to each death from phthisis.

The paper was discussed by a number who knew the region well and endorsed the statements of the speaker.

Meteorological Data of Colorado.—Dr. Samuel A. Fisk, of Denver, Colo., read a paper on this subject.

He dwelt on the known advantages of Denver. Its high elevation, a mile above sea-level, its dryness, etc. He classed Denver among the cool climates. The winds were from the south—dry winds. It is not the windy locality that many fancy. The climate is mild and there is less wind than in Philadelphia and New York. Colorado is peculiarly suited for life out of doors, due to pure air and sunshine.

The dust-storms in Colorado were made too much of by outsiders. In fact the dust did no harm, a fact too well known to admit of argument. He deemed the damp air of the East more harmful in lung cases than dust in the West.

Mr. Mark W. Harrington, of Washington, wished to supplement what had been said. He spoke of sunshine and wind, saying that the latter is a variable quantity. The velocity of the wind increases as we ascend. At the level of the street it is one thing, another half way up a high building, and still another on its top, as proven by the anemometer.

Dr. Fisk closed the discussion. He said the soil was dry and porous in Colorado. There was dust. Solar radiation made the atmosphere very dry. Patients from the East should be sent to a doctor in Colorado who knew the climate. He would advise on the proper locality.

Sensible Temperatures.—Mr. Mark W. Harrington, chief of the Weather Bureau, Washington, read a paper with this title. The term "sensible temperature" was one of his coining. It was the temperature felt by the skin, that which is felt at the surface of the skin, as on the back of the hand. On a sensible temperature depends our sense of comfort in hot weather. High shade temperatures do not necessarily mean discomfort, if the dew point is low. In may be 127° F. in the shade, but the temperature felt by the skin may be 45° below that, owing to the temperature at dew point. On a chart he showed the shade temperatures and dew points. Where the shade temperature and dew point intersected, it indicated the real or sensible temperature, being that felt by the individual.

By way of contrast, he made a comparison at 110° F.

and 115° in the far West, where such a high temperature may be less trying than 80° or 90° at the seaboard. The sensible temperature of El Paso, Tex., is similar to that of Erie, Pa.

There are localities in the United States where the thermometer may run up to 120° to 140° F. in the summer. The direct rays of the sun seem to exert a special stimulus on organic structures. The color of clothing is of less consequence than its looseness.

Dr. Guy Hinsdale dwelt on the value of the paper; it had unfolded a new and very instructive way of looking at the weather maps. In future, in consulting a weather map, we should make the correction, *i.e.*, the difference between shade temperature and dew point, to obtain the sensible temperature. All know of the necessity of making barometric corrections for reliable readings; the same now will be necessary for thermometric.

Dr. Robert H. Babcock, of Chicago, said the matter had a practical and important bearing on the clothing of our patients. Patients should wear woollen underwear all through the summer, that they may not be exposed to too sudden changes, particularly patients suffering from pulmonary diseases.

In closing, the Hon. Mark W. Harrington said that the subject was new. He expressed the hope that physicians would perfect it. He asked the question, what is the temperature of the vapor of perspiration? He answered his query by stating that in a freely perspiring surface the temperature must be greater than that for the evaporation of pure water, as perspiration is not a pure fluid.

Beriberi.—Dr. Judson Daland, of Philadelphia, read a paper describing several cases of beriberi, as studied by him at the Philadelphia Quarantine in a mixed crew in a vessel from the East Indies. Temperature normal; heart murmur; epigastric tenderness; finger-tips anæsthetic; again hyperæsthetic; blood examined found to be normal.

Second case: Patient weak; œdema in places; much dyspnœa on exertion; pulsating jugulars; extensive nervous disturbances; anasarcous; tricuspid murmur; examined blood, it was normal; searched for parasites in blood, none were found; anæsthesia of nasal and buccal mucous membranes; no knee jerk; lungs normal; dilatation of right and left ventricles; changes in cutaneous sensibility; in short, a case of neuritis.

The third case was much the same as Nos. 1 and 2. He deemed the cases interesting, as beriberi is rarely recognized in this country. It is a disease of the South. All his cases were sailors. Their diet had been salt-fish of poor quality and rice.

Etiology.—A disease of the East and West Indies. Poor diet is deemed a predisposing cause. Dr. Ashmead thought it due to causes produced in vessels with cargoes of sugar. A fermentative action. Men had no symptoms of scurvy. He thought it a peripheral neuritis. First the Egyptians in the crew were affected, then the others.

Dr. A. Gihon, of the U. S. Navy, was quite familiar with beriberi; had seen it during his sea service. Saw eight or ten cases last fall when the Brazilian men of-war were in New York Harbor. The cases described by Dr. Daland were admirable word pictures; such cases got well under good diet and improved hygienic conditions. He deemed beriberi a disease of malnutrition. He did not believe that sugar cargoes had anything to do with it. Certainly the Brazilian men-of-war were not sugar-laden. To repeat, he believed it to be a simple disease of malnutrition.

Dr. William H. Daly, of Pittsburg, thought it might be due to ptomaïne intoxication. There was no degeneration or disease properly so called. Thought that there might be digestive fermentation and subsequent ptomaïne intoxication.

Dr. Wolfred Nelson, of New York, asked Dr. Daland if any chemical or microscopical examination of the urine had been made.

Dr. Guy Hinsdale, of Philadelphia, deemed it a disease of nutrition, and referred to the views of Dr. Ashmead, who thought it due to carbonic-acid poisoning from cargoes of sugar.

Dr. Robert H. Babcock, of Chicago, asked if all recovered. Wanted to know if they were cases of acute cardiac asthenia with dilatation, such as we meet in typhoid and kindred conditions.

Dr. Daland, in reply, said, that the cardiac condition was very interesting; all recovered perfectly. He deemed it a neuritism and not a degeneration. As to Dr. Hinsdale's question, including that of carbonic-acid poisoning, he thought it a specific infectious disease associated with neuritis. Thought that the crew had been unruly and had been punished by way of the stomach. To repeat, the hearts returned to their normal condition. It was as Dr. Robert H. Babcock had supposed, a simple cardiac asthenia, due to want of tonicity in the cardiac muscle, where dilatation results from weakness. Replying to Dr. Wolfred Nelson, he said that but one test had been made of urine; he failed to remember that it was abnormal.

Dr. Wolfred Nelson referred to his having seen the disease while practising within the tropics in South America. Such cases generally died of general anasarca. Dr. Landon Carter Gray, in his book, included beriberi in his article on "Neuritis," and such it seemed to be.

Malaria.—Dr. William H. Daly, of Pittsburgh, Pa., read the next paper, having for title: "Some Practical Observations on So called Malaria." Dr. Daly thinks the malarial germ one of the infusoria, got in water in lowlands and swampy regions. Referred to cases due to drinking well-water from such lands. He did not deem vapors in marshes as productive of malaria. Some believe that malaria invades at night, that the poison is breathed into the system. He believes that the poison, or germ, is in the water. The habitat of the germ is in the soil. That water in malarial districts always contains the germ. So-called malaria is a water-born disease, the same as cholera.

Malarial fever in the United States is clearly a preventable disease. In the Southern States animals suffer from it. Well-water in the South caused malaria. Those drinking pure cistern-water escaped. The latter were healthy and ruddy. To repeat, malaria gets into the body through the food channels.

Dr. Gihon, of the United States Navy, thought it due to aqueous vapor as well.

Dr. Wolfred Nelson referred to an extended visit by him to the island of Cuba, and related the experience of his friend, the late Dr. John Hartmann, formerly physician to the Uruguay Mining Company, near Santiago de Cuba. The company employed hundreds of Spaniards. They were divided into a day and a night shift. The night-gang slept by day and took a hearty meal on going to work. The day-gang, of course, slept by night. Not a single case of malaria in any of its multiple forms developed in the night-gang, while the men who slept by night and worked by day had malarial and bilious remittent fevers constantly.

Dr. William H. Daly closed the discussion by stating that in five years he believed his views would be accepted by the profession at large.

Physical Signs of Œdema of the Lungs.—Dr. W. C. Glasgow, of St Louis, Mo., read a paper entitled "The Physical Signs of Cellular Œdema of the Lungs, Considered in their Relation to the Pathological Changes." The paper dealt with cases in his practice. He deems the disease due to sepsis. He detailed the symptoms during life, and the changes found post mortem.

Said disease might be due to a gas-producing organism. The signs and symptoms are very perplexing, and often contradictory. He got râles resembling bronchitic râles. Said that there were different degrees of infiltration in the cell-walls and bronchial mucous membrane, not as stages but as types. Infiltration was sudden, and resolution may occur as quickly.

The Grosse Isle Quarantine Station.—Dr. Wolfred Nelson, of New York, informally brought to the attention of some of the members a number of photographs made by him last fall while at the Grosse Isle Quarantine Station, in the St. Lawrence, below Quebec. The situation is an ideal one, an island twenty-four miles down the river, six miles from one and four miles from the other shore. It was an old time and thoroughly organized Government station; forty buildings were up; the majority fully equipped with the latest appliances. They were divided into first, second, and third classes, all in different localities. In case of an emergency three thousand immigrants can be housed. The disinfecting plant is wholly of Canadian manufacture. So extensive is it that the effects of one thousand immigrants can be disinfected daily—dry heat, then live steam at a temperature of 230° F.

Dr. F. Montezambert, Superintendent of the Dominion Quarantine System, is in charge. He has a trained staff under him. There is a special staff for service afloat. Canada to day has a station second to none.

The Society was then adjourned, to meet next year in West Virginia.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting February 28, 1894.

George C. Freeborn, M.D., President.

Papillomata and Papillomatous Cysts of the Ovary.—The President presented a series of specimens of papillomata and papillomatous cysts of the ovary.

Case I.—These specimens were removed by laparotomy by Dr. George M. Tuttle. The patient was thirty years of age, and the mother of two children. Four months previous to the operation she first noticed a tumor in the left iliac region. Since then she had lost flesh and had had considerable pain. At the time of operation, the abdominal cavity contained a small quantity of clear serum. A large papillomatous cyst, adherent to the omentum, was found on the left side, and a papillary mass on the right. The left ovary consisted of an irregular-shaped, lobulated mass of papillary growths, measuring 8½ ctm. in its long, and 6 ctm. in its short diameter. The slightly enlarged tube was attached to the mass by an elongated and thickened mesosalpinx. Its fimbriated end was occluded and rounded off. Section through the mass showed an irregular shaped ovary containing a few follicular cysts embedded in the papillary mass. The left ovary was reduced to a thin-walled oval cyst, to the upper surface of which was attached a slightly enlarged tube. Growing from the upper and anterior portion of the external surface of the cyst, and extending to the tube, was a lobulated papillary mass, measuring 9½ ctm. in length, 7 ctm. in thickness, and projecting 5½ ctm. above the surface. On the posterior surface of the cyst there were also a few small isolated papillary masses. The tube was slightly enlarged, its fimbriated end occluded, and its surface covered with adhesions. Section showed a small portion of ovarian tissue containing a few small cysts, forming the upper portion of the cyst-wall, the remainder being thin fibrous tissue The internal surface of the cyst was studded with papillary outgrowths, varying in size from that of a pin head to that of a cherry. From the surface of the remains of the ovary there was an outgrowth of papilloma. At the external end of the remains of the ovary was a second cyst, containing a small papillary mass.

Case II.—These specimens were removed from a patient in the service of Dr. C. Cleveland, in the Woman's Hospital. She was unmarried, and thirty years of age. Ten months previous to operation she noticed an enlargement of the abdomen, and six months later three gallons of a light brown fluid were removed from the peritoneal cavity by tapping. At the operation, six months later, two and a half gallons of the same kind of fluid were removed. The right ovary showed an oval cyst, 7 × 5 ctm., from the end of which projected an irregular, lobulated papillary mass, 10 × 8 ctm. Longitudinal section through the cyst and papillary mass showed that the cyst grew from the end of the ovary. It was thin-walled and had a lobulated papillary mass, 4 × 2½ ctm in size, growing from the internal surface of the cyst-wall, and appeared to be continuous with a similar mass attached to the outer surface of the cyst. The remains of the ovary were triangular in shape, measured 1½ × 4½ ctm., and were surrounded by a mass of papillary growth. The papillary mass was divided into three lobes, each of which was attached to the ovary by a distinct pedicle. The left ovary was an irregular, papillary mass, 11 × 8½ ctm. Section through the mass showed its central portion to be composed of an oval ovary, 5 × 3 ctm. The ovary contained several small cysts. Along the upper surface of the ovary there was attached a slightly enlarged Fallopian tube. The papillary mass was composed of three lobes, which were attached to the surface of the ovary by distinct pedicles. Two of these were rather broad, the third was long and slender, and was attached to the outer end.

Case III.—These specimens were examined at the request of Dr. George M. Tuttle, who had removed them from a married woman, fifty-two years of age, the mother of four children. The menopause had occurred six years previous. Eight months before operation she noticed an enlargement of the abdomen and œdema of the lower extremities. At the time of the operation a tumor of the abdominal cavity was found extending above the umbilicus. The inguinal lymph nodes were enlarged. Upon opening into the peritoneal cavity a moderate amount of clear serum was found. On the right side was a tumor growing from the ovary and extending out between the folds of the broad ligament. The omentum was adherent to its surface. The left ovary and tube were normal. The omentum showed a papillary mass the size of a cherry attached to its lower border. Microscopical examination showed a small papillary mass distributed very generally over the surface of the trabeculæ.

Case IV.—The specimen was removed from a married woman, thirty years of age, who was in the service of Dr. C. Cleveland in the Woman's Hospital. She gave a history of gradual enlargement of the abdomen extending over a period of six months previous to her admission. During the six weeks prior to operation there was a rapid accumulation of the ascitic fluid, with loss of flesh and strength. Laparotomy was performed and revealed both the ovaries and tubes converted into papillary masses, and so firmly adherent to the pelvic tissues that they could not be removed. The omentum was found adherent to the uterus and intestines and filled with a mass of small cysts. The portion of the omentum presented was removed and the abdomen closed. The patient died twelve hours after the operation, of exhaustion. No autopsy was permitted. The specimen consisted of a rectangular piece of the omentum, measuring 12½ × 11 ctm., with an average thickness of 20 mm. The entire specimen consisted of a mass of small cysts, thin-walled, and containing papillary masses and a clear, thin fluid.

Case V.—This specimen was removed by laparotomy from a woman, twenty-six years of age, who was admitted to the service of Dr. Outerbridge in the Woman's Hospital. The history stated that she was married, but had had no children. Two years previous to her admission she had sharp pain in the left iliac region; one year later she noticed a tumor and also œdema of the lower extremities. The specimen was removed by laparotomy, and consisted of four thin-walled cysts grouped around a central dense mass, from which there sprung an irregular papillary growth. Section showed all the cysts more or less ovoid in shape, the largest measuring 10 × 8 ctm.; the next in size, 9 × 6 ctm.; the next, 8 × 5½ ctm., and the smallest, 6 × 4½ ctm. The interior of all the cysts was more or less studded with papillary outgrowths. The central dense mass was the remains of the ovary, from the surface of which grew the papillary mass.

Case VI.—This specimen was removed by Dr. F. H. Markoe. It was a multilocular cyst 10 × 12 ctm. The Fallopian tube was attached to the surface of the cyst. Section showed three principal cysts with thin walls, the internal surfaces of all being studded with various-sized papillary outgrowths.

A Cylindroma of the Scalp.—Dr. E. K. Dunham presented a cylindroma of the scalp. The tumor was about one and one fourth inch in diameter, one half inch thick, and lenticular in shape, and was situated in the anterior portion of the scalp in the median line. It had been growing slowly for two years, and was regarded as a recurrence in the cicatrix left after the excision of an old wen. After the removal of this tumor the patient, a man aged seventy, lived for one year without any sign of recurrence, and then died of apoplexy. An examination of the first sections had led him to think it was an epithelioma, but careful examination of the thinner sections showed it was a sarcoma, and one in which certain elements had undergone hyaline degeneration. Microchemical tests were made for hyaline material, but with negative result. The specimens exhibited under the microscope showed the alveoli filled with small, round cells, and among these cells small hyaline bodies. The speaker said it had occurred to him that these hyaline bodies were degenerated capillary vessels, but he was doubtful about this because he had been unable to find any transition forms, and moreover, there was hyaline degeneration not only of the blood vessels, but of the fibrous tissue, as the capsule exhibited the same degeneration.

Dr. E. Hodenpyl agreed to the diagnosis of cylindroma, but objected strongly to the use of the term "cylindroma," which was vague and unsatisfactory.

Congenital or Infantile Myxœdema.—Dr. W. P. Northrup presented photographs of three cases. These cases were being treated by the internal administration of the glycerine extract of the yearling sheep's thyroid. It had been found that a daily dose of three drops kept the temperature at about the desired point—100° F. The photographs showed very well the peculiar physical characteristics of these children.

Carcinoma of the Liver, Stomach, and Lungs.—Dr. E. Hodenpyl presented specimens from a case of carcinoma of the liver, stomach, and lungs. The case was remarkable on account of the enormous extent of the lesion, the very short duration of the disease, and the very moderate discomfort which it caused. The patient was a man, forty six years of age, whose family history and previous history were negative. His last illness dated back to the latter part of October, 1893, when he began to experience a heavy sensation in the upper part of the abdomen, and a distress after eating, which, however, was not aggravated by eating. There was no vomiting, pyrosis, or eructation of gas. He gradually developed dyspnœa. When admitted to hospital, on January 31st, he was moderately emaciated and pale; the urine was normal. Physical examination showed the heart and lungs to be normal. Hepatic dulness began in the fifth space, and ended two inches below the free border of the ribs. The spleen was not enlarged. There was a good deal of constipation, but no vomiting, while he was in the hospital. He died comatose. At the autopsy the left lung was found studded with a moderate number of yellowish-gray nodules. The right lung was considerably compressed, the liver was enlarged, the gall bladder normal, and the cystic duct pervious. Extending along the entire length of the lesser curvature of the stomach, but not involving either the cardiac or pyloric orifices, was a large carcinomatous nodule the size of a small orange, and adjoining it a thickened portion of new-growth and a large area of ulceration. The liver, together with the pancreas and stomach, weighed fourteen pounds.

Hypertrophy of the Prostate; Carcinoma of the Bladder; Hydronephrosis; Chronic Bright's Disease.—Dr. Hodenpyl also presented specimens removed from a man, sixty-six years of age, who was admitted to the hospital on February 20th. It was impossible to obtain an accurate history from him. He had been quite intemperate. He said that about two months before admission he became very obstinately constipated, and there was inability to urinate except in small drops. On admission, there was œdema of the legs, scrotum, and penis; his temperature was 100° F.; respiration, 20. The urine was very bloody, alkaline, had a specific gravity of 1.013, and contained seventy-five per cent. of albumin by volume. The daily quantity of urine voided for three successive days was six, two, and sixteen ounces respectively. The urine was drawn by the catheter while he was in the hospital, and was always very bloody. Physical examination showed fluid in the abdominal and pleural cavities.

The chief point of interest in the case was found on the peritoneal surface just adjoining the right kidney—a series of intercommunicating sacs, many of them ending in blind pouches with thickened edges. Some of them were ulcerated. The ureter passed over this curious mass into the kidney. The speaker said he was unable to explain this condition except on the supposition that it was either a secondary growth or fœtal remain. He would report upon it more fully at another time.

Dr. T. S. Southworth presented the lungs from the twin of the child whose lungs were presented by him recently. This child was fifteen months old, and weighed at birth four pounds and a half. Last May it had severe pertussis, and in the third week of the disease a bronchopneumonia for six weeks. After this it gained slowly up to five weeks ago. Two weeks ago it developed fever, and fine crackling râles over the chest, anteriorly and posteriorly, with a temperature of 100° to 103° F. It died suddenly. At the autopsy the left lung showed adhesions posteriorly, and the right lung general firm adhesions, evidently older than in the other lung. The bronchial glands were markedly enlarged on the right side, but were not cheesy. There was consolidation and a fairly uniform white mottling of the right lower, right middle, and posterior half of the right upper lobes. There was also consolidation of the posterior half of the lower lobe of the left lung, with the same mottling. The spleen was much enlarged and congested. The mesenteric glands were not enlarged. This child was also supposed to be tubercular, but the lung showed the form of broncho pneumonia not infrequently mistaken for tuberculosis. It was worthy of note that notwithstanding the history the bronchial glands were not cheesy.

Abscess of the Liver Mistaken for Empyema.—Dr. J. M. Byron reported this case. The case occurred in Bellevue Hospital, and the diagnosis of empyema was made because exploratory puncture and the physical signs pointed to this condition. An opening was made on the right side at the usual point, and some pus withdrawn. The man died, and on autopsy absolutely nothing was found in the pleural cavities except a very slight pleuritis on the right side. In the posterior and upper part of the right kidney, however, was a very large abscess cavity, which communicated with the operation wound. The diaphragm was intact. There was no ulceration in the intestines, or anything to account for this abscess in the liver.

Exophthalmic Goitre.—Dr. Henry Power reported a case of exophthalmic goitre treated with the thyroid extract; death in six weeks. The only other case of the kind, so far as he knew, had been reported by Dr. Owen, in the *British Medical Journal*. His own patient was a Swedish domestic, twenty-four years of age, in whom rather large doses of the thyroid extract were used—seven to nine drops three times a day. At first there was general improvement, and shrinkage of the tumor to half its former size, but this was followed by a return of the former condition, and by a deterioration of her general health. The dose was quickly reduced, and finally stopped, but three weeks after the last dose the patient became comatose and died. At the autopsy, which was made twenty four hours later, it was noted that there

was marked emaciation, together with enlargement of the thyroid. The heart, lungs, and kidneys were normal; the uterus was small and of the infantile type; the spleen was not enlarged. The thymus was present; it measured 3½ × ¾ × ½ inches, and weighed 13 gm., after partial hardening. The thyroid showed great symmetrical enlargement, and weighed 40 gm. after partial hardening. The brain could not be examined. Microscopical examination of the thyroid showed the stroma normal, and the epithelium greatly proliferated. Some of the alveoli were lined with cuboidal epithelium, others with cylindrical cells, while others again had no regular lining. The stroma of the thymus appeared to be normal; the cells stained with difficulty. The liver contained some fat. The kidneys were lobulated and contained hyaline casts. They also showed degeneration and congestion.

Cancer of the Œsophagus.—Dr. Henry P. Loomis presented the specimen. The patient was a man, fifty-three years of age, who had an excellent family history, and also a good previous history, except that he said he had had a slight bronchitis for many years. His last illness began last August with anorexia, uneasiness in the epigastrium, and slight vomiting. The pain was most intense in the left hypochondriac region and near the xiphoid cartilage For two months he could only take solid food with difficulty, and then finding that solid food caused pain he swallowed nothing but oatmeal and milk. On admission he was very greatly emaciated, had a haggard, apathetic expression, and vomited curdled milk. Physical examination of the abdomen showed an area of flatness about four inches in diameter, with its centre one inch below the xiphoid cartilage.

The autopsy was made thirty six hours after death. No pathological lesion was found in any of the organs or tissues until the stomach and œsophagus were opened. A firm, dense, cancerous infiltration was found in the wall of the lower portion of the œsophagus and the œsophageal end of the stomach. About three inches of their walls were infiltrated with a dense mass which narrowed the opening of the œsophagus into the stomach to such a degree that it was with difficulty that an ordinary penholder could be introduced down the œsophagus. There was no ulceration or involvement of the rest of the stomach wall. The infiltration presented the ordinary appearance of a scirrhous cancer. There was marked atrophy of the intestines. The patient apparently died of inanition due to mechanical obstruction, which interfered with the introduction of food into the stomach.

Cancer, the speaker said, was the most frequent form of tumor met with in the œsophagus, and statistics showed that the seat of the tumor in this case was the most frequent portion involved. The extreme narrowing of the tube was due partly to the infiltration, and partly to the contraction of the newly formed connective tissue as the result of the irritation of the new growth. The dense infiltration no doubt produced the feeling of obstruction which was constantly referred to by the patient during life. The absence of ulceration was unusual. The œsophagus and stomach at the site of the cancer were tightly bound to the cellular tissue behind them. The tumor was diagnosticated during life, and an operation advised. If this advice had been followed, no doubt the patient's life would have been prolonged considerably by the establishment of a gastric fistula.

Primary Tumor of the Heart Wall.—Dr. H. P. Loomis presented a specimen of tumor of the heart wall which had caused sudden death. At the request of the coroner a post mortem examination was made on W. J——, thirty-five years of age, who was found dead on the floor of his bedroom by the servant who came to awaken him in the morning. A friend, in whose room he had spent the previous evening, testified that he left him about eleven o'clock, apparently as well as ever; but on being questioned further, the witness recalled the fact that his friend had complained of some distress over his heart two or three times while they were together. The man must have died immediately on reaching his bedroom, for he was found stretched on the floor with his hat grasped in his hand. Careful inquiry was made of his friends, who stated that he had not been sick for years, nor had he even complained of feeling ill during the month preceding his death. He had attended regularly to business. He was a moderate drinker, but at times indulged to excess. No syphilitic history could be obtained. The autopsy was made twelve hours after the body was found. He was a robust man, of excellent physique, and weighed one hundred and seventy-five pounds. There were no marks of external injury. The liver and kidneys showed the lesions of extreme passive congestion, with moderate cirrhosis of the liver. A most careful examination of all the other organs, including the brain, failed to reveal the slightest abnormality until the heart was opened. Here a lesion was found—one of the rarest met with in post mortem examinations. A circumscribed tumor of a yellowish-white color, firm in consistency, non capsulated, was found embedded in the anterior wall of the left ventricle. Its dimensions were ¾ × 1¼ × 2 inches, and it involved over one-third of the wall of the left ventricle. Neither the endocardium nor the pericardium over the tumor was involved. The heart weighed sixteen ounces. The left ventricle was very much dilated, and as a result there was marked insufficiency of the mitral valve. There was no hypertrophy of the heart wall. The valves were normal, as was also the endocardium. A large, soft, red, non-adherent blood-clot filled the cavity of the left ventricle. The right ventricle was free from blood, slightly dilated, and its wall was somewhat thickened. The coronary arteries were normal. The thoracic and abdominal aorta showed the lesion of an extensive aortitis, involving the greater portion of its inner coat. A section cut so as to include the heart wall and the greater portion of the tumor showed on microscopical examination that it was composed of small round cells, with here and there, near the centre, cheesy spots. In a few places, giant cells could be seen, as also amorphous basement substance between the round cells. In places young connective-tissue formations could be seen. The tumor was moderately supplied with small blood-vessels in its outer portion. It was not encapsulated. The round cells could be seen running between the muscle fibres in its external zone. Sections of the tumor were stained for tubercle bacilli with negative result. Gram's method failed to reveal the presence of any micro-organisms. From a careful examination of all portions of the tumor an unqualified diagnosis of a syphilitic gumma was made. This diagnosis was later confirmed by Dr. T. M. Prudden, who examined the specimen.

Primary tumors of the heart are exceedingly rare, although secondary tumors are not of infrequent occurrence, especially secondary carcinomata. Virchow in his Archives, vol. xv., describes the following tumors as being found in the heart wall: sarcomata, fibromata, lipomata, myxomata, and syphilomata. The last he says is among the rarest tumors met with. This is the second case of primary syphilitic gumma which the speaker had met with in the last ten years, the other case being that of a prostitute, thirty years of age, who died of lobar pneumonia. The present case is also of interest because it was no doubt the indirect cause of the man's sudden death, which must be explained by the sudden over distention and inability of the left ventricle to empty itself. Nearly one-half the muscle fibre of the left ventricle wall was destroyed by the new growth.

Syphilis is known to affect the heart in two ways, viz.: 1, by the formation of a gummy tumor, as in this case; and 2, by setting up an indurated myocarditis, the localized and extensive fibrous indurations in the muscle tissue being generally associated with a fatty degeneration of the muscle fibre. Cheesy masses are often found in these indurated areas, and the question has been raised as to whether they may not be gummata in process of absorption. Lancereaux mentions two cases of waxy de-

generation of the heart wall which he refers to as one of the manifestations of tertiary syphilis, but his observations have not been confirmed by other observers. No doubt syphilitic gumma in various stages of development and metamorphosis is the most characteristic lesion of tertiary syphilis affecting the heart.

Carcinoma of the Wall of the Stomach.—On behalf of Dr. Le Fevre, Dr. Loomis also presented a specimen of carcinoma of the wall of the stomach. The specimen was removed from a married woman, thirty-one years of age, whose family history was good. She had enjoyed good health up to six months after her last confinement, or up to one year and nine months ago. She was slightly anæmic at this time, but quickly recovered. Five months later she came under Dr. Le Fevre's care, complaining of very severe pain in the stomach, accompanied by vomiting. Her weight had been reduced in a short time from one hundred and forty pounds to one hundred and fifteen. She improved temporarily under tonic treatment. Four months later there was extreme pain in the epigastrium, radiating through to the angle of the left scapula. With this there was incessant vomiting and also some fever. Six days later, the thickened wall of the stomach was mapped out by physical examination. She then passed from under his observation. She was reported to have suffered constantly. She never vomited blood. At the autopsy, the body was found to be extremely emaciated; the lungs, liver, and intestines were normal; the uterus and ovaries were also normal. The stomach was adherent to the spleen, and these were adherent to the upper portions of the intestine. There was very extensive cancerous infiltration of the wall of the stomach, beginning at the pylorus, and involving by far the greater portion of the stomach. Incidentally, the heart was of interest, for, while presenting no organic disease, it was as small as the heart of a child.

Dr. Byron said he had examined some of the sections of the tumor of the heart wall, and the structure was not at all characteristic of gumma of the heart. The round-cell infiltration was very extensive and uniform, and all of the cells seemed to be nearly of the same age without any discernible degeneration in any portion of the tumor. The giant cells, which reacted to eosin almost like muscular tissue, seemed to him to be simply muscle fibres in which the inflammation had given rise to the proliferation of the muscle nuclei.

Dr. Loomis said that as the case had been variously diagnosticated as interstitial myocarditis, abscess of the heart, sarcoma of the heart, etc., he would be very glad to have the specimen examined by the Committee on Microscopy. He did not think, however, that it was possible that the giant-cells were really muscular nuclei.

The specimen was referred to the Committee on Microscopy.

The society then went into executive session.

Stated Meeting, March 14, 1894.

George C. Freeborn, M.D., President.

Tuberculosis of the Bladder and Kidneys.—Dr. W. G. Le Boutillier presented specimens from a case of the above. They were removed from a man thirty-five years of age, who had one testicle removed ten years before, probably for tubercular disease. There was no history of the beginning of the tuberculosis. At the time of death there was tuberculosis of the lungs, of one hip-joint, and of several vertebræ. The pelvis of each kidney contained a mass of cheesy material and several cheesy masses also in the cortex. The right ureter was much dilated, but there was no evidence of obstruction. While the patient was under observation some of the urine was injected into a guinea-pig to confirm, if possible, the tubercular nature of the disease. The guinea-pig was found dead about eight weeks later, and examination showed cheesy masses at the site of the inoculation and also general peritonitis and tubercular lesions of the lungs and spleen. Tubercle bacilli were found in the patient's urine.

Bovine Tuberculosis.—Dr. George P. Biggs presented portions of organs showing the characteristic lesions of bovine tuberculosis. The specimens were brought to him by a veterinarian, who stated that large numbers of tubercles were found in the lungs, heart, mesenteric glands, mediastinal glands, peritoneum—in fact in all of the organs. The animal was a Jersey cow, and its milk had been used up to about two weeks before the animal was killed. It had been slightly ill for a few weeks, and had had a slight dry cough, which, however, two veterinarians had said was of no significance. The animal also had a good deal of difficulty in breathing, and examination showed a large number of dry râles. The specimens presented comprised portions of the liver, spleen, lungs, mesenteric glands, and udder. In the section from the udder there were no distinct giant cells, but rather epithelioid tubercles. The tendency to caseation was very marked. The speaker said these caseous masses usually became encysted, and after considerable time underwent calcification. Unfortunately no examination was made of the milk. Among the characteristic features of tuberculosis might be mentioned, (1) a series of outgrowths from the serous membranes often attached together like bunches of grapes; (2), the tendency to calcification; and (3) the proneness to the formation of fibrous tissues.

Dr. Le Boutillier asked for further information regarding the diagnosis of bovine tuberculosis. He understood that recently the diagnosis had been made by injections of tuberculin.

Dr. J. S. Ely said that for some months past he had been examining material sent him by the cattle inspectors of the State Board of Health. They have been using tuberculin quite extensively and with good results. Last November he went to Barren Island to see some condemned animals slaughtered. Out of the seventy-two cattle, sixty-eight had given the characteristic reaction with tuberculin, and after slaughtering, just sixty-eight of the animals were found to be tubercular. The normal temperature of cattle was higher than in the human subject, about 102° F. After the injection of the tuberculin, the temperature rose within seven hours to 104° or 105° F., and in the course of four or five hours more, fell to the normal. This was considered the typical reaction. The herd referred to was a valuable one, being worth about thirty thousand dollars, and consequently the owner had employed several veterinarians to examine the cattle. One prominent veterinarian said they were not tubercular, and another coincided in this opinion, yet many of the animals when slaughtered showed lesions nearly as pronounced as those seen in the specimens just presented.

Dr. T. M. Prudden said that a farmer came to see him recently in regard to a herd of Jersey cattle which he suspected had become infected with tuberculosis. Only about thirty cattle seemed to be sick, and as these thirty gave the characteristic reaction with tuberculin. they were killed, and were found to be tubercular. The owner then determined to sacrifice an apparently healthy animal to determine still more definitely the value of this test. An animal which did not give the reaction with tuberculin was slaughtered and was found to be free from tuberculosis. The power of this breed of cattle to produce milk and butter seemed to be at the expense of their resisting power to tuberculosis. The very long series of experiments of Dr. Ernst, published before the Association of American Physicians in Washington some years ago, and a similar series in Germany, showed that it was not at all necessary to have any involvement of the udder to have tubercle bacilli in the milk.

Osteosis of the Skin of the Foot.—Dr. Warren Coleman presented the specimen. He said that in March, 1892, Dr. Sherwell presented a case to the Dermatological Society for diagnosis. The patient, a girl six years of age, of American parentage, had an erosion in the sole of the left foot which the mother had first

noticed about two and a half years previously. It was a thickening of the skin and subcutaneous tissue, occupying about one-third of the plantar surface of the foot, chiefly under the os calcis, and a little to the outer side. It was learned that a year and a half after the lesion in the sole had appeared, the fourth toe became involved, and gradually increased in size, the skin of the entire toe taking part in the process, though the lesion was most advanced in the distal phalanx. The enlargement was symmetrical, and the toe attained a diameter of 1 ctm. At that time Dr. Sherwell described the condition as follows: "The lesion now consists of a plaque of cartilaginous hardness, studded here and there with tubercular nodosities, about six in number, the whole occupying about one-third of the external plantar surface of the left foot. The skin and subcutaneous cellular tissues are all involved in the process, still the plaque can be moved relatively freely over the subjacent tissue. The epithelial tissues, while somewhat thick and horny, present no other unusual features. There are few subjective symptoms while the foot is at rest, but on account of the hardness it is difficult to walk upon, it seeming to act as a foreign body without the irritation the latter would cause. The little patient always walks on the ball of that foot. The lesion on the fourth toe is of the same relatively painless character, and is curiously clubbed on top, and the peculiar cartilage like feel is also present. On no other part of the limbs or body is anything that is abnormal. The child is of healthy parents as far as can be ascertained, and is a healthy child. I cannot class the trouble as scleroderma or carcinoma *en cuirasse*, and present her for diagnosis."

In December, 1892, the plaque and fourth toe were removed by operation and were hardened in alcohol. It was noticed at the operation that in cutting out the plaque the knife met with more resistance beneath it than normal subcutaneous tissue would have offered, even in the sole of the foot.

It was learned from Dr. Sherwell that the growth had recurred and was now advancing. The scar was adherent to the bone, and in front of the scar the skin and subcutaneous tissue were infiltrated with a substance which from its hardness and resilience seemed to be cartilage. It was of new formation, having appeared since the time of the operation. Dr. Piffard decalcified a portion of the growth in a two per cent. mixture of nitric acid and ninety-five per cent. alcohol, and as an examination of sections from this piece showed a general infiltration of the skin with bone, rather than a distinct tumor formation, he suggested the name "osteosis." The body of the plaque, its advancing edge, and the toe were examined. The latter was cut at two different levels—through the body of the phalanx, and through the articular cartilage—with a view of determining the origin of the process. The staining of the cells was somewhat interfered with by the use of this mixture for decalcification. Twenty different sections were studied.

The sections through the body of the plaque showed cancellous bone close up to the epidermis. The spicules varied in size and shape, and were irregularly distributed throughout the tissues. The interspaces were filled chiefly with fat-cells, blood-vessels, and a loosely woven connective tissue. Small nerves were found here and there. The sweat-glands and their ducts appeared normal. In this part of the growth the spicules were the most abundant, which would account in part for its greater hardness, but they were also smaller. There were irregularities in their size and shape apparently due to absorption. Frequently distinct rows of cells might be seen along the sides of the spicules, but as a rule they did not lie under a definite membrane. Large multinucleated cells were sometimes associated with them, especially where the spicules were thinnest. Mingled with the fat-cells generally in the interspaces was a tissue of marrow-like structure, consisting of uni-nucleated cells a little larger than lymph-cells, the nucleus occupying nearly all the protoplasm. The large multi-nucleated cells occurred with these, and fine connective-tissue fibres ran among them all in different directions. Some of the spicules consisted merely of a homogeneous ground substance with rounded or flattened cells scattered through it; in others, the cells were branched, and arranged in irregular rows, or were disposed in concentric rows around a central opening. No distinct fibrillation could be made out in any of them. As a rule, the spicules were composed of irregular lamellæ, between which were branching lacunæ, filled with bone corpuscles. Small blood-vessels were included in the larger masses of bone, and in rare instances the lamellæ were arranged concentrically around them, but there was a lack of regularity characteristic of the Haversian system in the disposition of the bone corpuscles. The connective tissue immediately under the epidermis was very dense, in fact, was almost tendinous in structure.

The edge of the plaque was not so thick, and contained less bone than the part just described. It contained also masses of cartilage. Some of the cartilage-cells were branched. There was also reason to believe that a transformation of fibrous tissue into cartilage was taking place, for cells immediately adjacent to cartilaginous masses might be seen increasing greatly in number, and arranging themselves between bundles of dense fibrous tissue, and becoming flattened out. They were of the same size, shape, and appearance as the outermost cells of the cartilage, and merged imperceptibly into them. They corresponded very closely with cells in a like situation in an ossifying tibia from a six months' fœtus. There was an entire absence of rows of osteoblasts around these centres. This transformation was suggested in certain sections from the older part of the growth, but in them, as a rule, the ossification of cartilage already formed was the most prominent feature. The method by which the cartilage extended would explain the absence of a periosteal layer, but without a periosteum it was not so clear why the osteoblasts arranged themselves in definite rows along the sides of the calcareous cartilages.

In all essential details ossification was proceeding regularly. Many of the spicules had ossified only so far as the deposition of calcareous granules in the cartilaginous matrix without any noticeable change in the appearance of the cells. As ossification proceeded the cells swelled up, but did not, as a rule, arrange themselves in any characteristic manner. Rows of osteoblasts developed along the sides of the cartilaginous masses, with or without the occurrence of the large multi-nucleated cells or osteoclasts. Then the irruption commenced. The irregular openings found in many of the spicules might be explained in this way, for they contained both kinds of cells. The presence of these large cells, or osteoclasts, in certain of the spicules would also suggest this formation having burrowed there from the side. Only in exceptional instances did the osteoblasts lay under a definite membrane. Where ossification was complete, both osteoblasts and osteoclasts had disappeared, and the bone had an irregularly lamellar or concentric arrangement. The lacunæ were branched, and filled with bone cells. There were several areas in which typical ossification occurred, with marked swelling of the cells, their arrangement in definite rows, irregular absorption of the cartilaginous matrix, and the entrance of blood-vessels into the spaces thus formed.

A section through the body of the phalanx of the toe showed a notable absence of new bone in the dermis and sub-dermic tissues. An excessive development of very dense, almost tendinous, fibrous tissue was the principal cause of the increased diameter of the toe. All the normal elements of the skin were present. The central canal of the bone contained spicules of irregular shape and arrangement, with fat cells and blood-vessels filling the interspaces. The number of bone corpuscles was noticeably small and there were no osteoblasts along the sides of the spicules. In the cartilaginous ring which surrounded these and to which they were attached, ossi-

fication proceeded regularly. But there was no periosteum even here, and at irregular intervals around its periphery the transformation of fibrous tissue into cartilage, with a consequent extension of the ring, was more evident than in sections from the edge of the plaque. Where the cells were distinctly cartilage-cells, and even where they had begun to swell and arrange themselves in a definite manner for ossification, fibrous bands could be seen running among them. Instead, however, of the cells arranging themselves in rows at right angles to the advancing line of ossification, they became grouped, apparently from repeated subdivision, the number of cells in such group being a multiple of two. At this point absorption began with the subsequent building up of the spicules that were left. The cells in the outer part of the cartilage where it was extending were flattened, and some of them were slightly branched.

Concerning the sections through the articular cartilage, it was worthy of note that a true epidermic formation, consisting of all the layers quite perfectly developed, ran in crescentic form one-fourth the way around the bone, and almost immediately adjacent to it. A number of sections, as well as the block from which they were cut, were carefully examined to make sure that this did not result from an accidental infolding of the skin.

It would appear that primarily there was a hyperplastic formation of very dense connective tissue, that this was transformed into cartilage, which was extended by a further transformation of the adjacent fibrous tissue and the subsequent ossification of the cartilage. This transformation of fibrous tissue into cartilage could not be regarded as a pure metaplasia because of the marked cell-proliferation accompanying it. There was nothing to warrant the belief that the lesion originated from the periosteum or pre-existing cartilage. The increased size of the toe was principally due to an excessive development of fibrous tissue. The extension of the cartilaginous ring seemed to be simply a part of the general process, and not the starting point of it. If the process had begun by an extension of the pre-existing cartilage it would be reasonable to suppose that the plaque would have been attached to the underlying bones, but such was not the case. While it was true that bone was present throughout the entire depth of the sections, ossification had been completed in the parts just beneath the epidermis. As it was probable that the ossification began in the cartilage first formed, the speaker thought the transformation first occurred in the dermis itself, or immediately below it. Metaplasias, both physiological and pathological, were of common occurrence, but as Ziegler had said, these metaplasias "are confined to the connective tissues; fibrous tissue, cartilage, bone, mucous tissue, and adipose tissue, are, so to speak, potentially convertible." The sesamoid fibro-cartilages formed in tendons might be cited as instances of the transformation of fibrous tissue into cartilage. Arterial sclerosis sometimes resulted in the formation of cartilaginous patches in the walls of the vessels. In myositis ossificans there was a transformation of fibrous tissue into bone. The proneness of hyaline cartilage to ossify was well known.

The most rational explanation of the etiology of this case seemed to be that it was due to a congenital disposition to hyperplasia and metaplasia of the connective tissue in the derma and subdermic structures. Syphilis might be excluded, and it could not be ascribed to any special irritation resulting in an inflammatory condition, as the history showed a notable absence of signs of inflammation. When bones developed in abnormal situations in the body they were usually the result of long-continued irritation leading to inflammation. In rider's bones we had an example of bone formation from long-continued pressure, though the ossification might be at times of syphilitic origin.

Occlusion of the Ileo-cæcal Valve by a Plug of Mucus: Extreme Interstitial Emphysema of the Lungs.—Dr. James Ewing presented the lungs, ileum, and colon which had been removed from a child who died fourteen hours after birth. The presentation was L. O. A. and the labor natural. The second stage lasted one hour. There was considerable asphyxia of the child at birth, so that four mouth to mouth insufflations were made, after which it seemed to breathe naturally. It was not long, however, before the breathing again became bad, and the child cyanotic, and these symptoms persisted until death. One hour after death the autopsy was made. The abdominal wall was tense and protuberant. The liver, which had been pushed upward, descended as the abdomen was opened. The lower six inches of the ileum were found collapsed. Above this point the intestine and stomach were excessively distended with gas. The lower two feet of the ileum contained a tough cord of mucus which protruded through the ileo cæcal valve and completely occluded it. Six inches above the valve it formed a plug which was not easily detached. The lungs showed great compression, especially in the lower lobes, and while they were largely atelectatic they were not consolidated. Scattered over both lungs were many prominent vesicles showing extreme interstitial emphysema. Two or three large vesicles covered two-thirds of the internal surface of the right lung. The cerebral sinuses were intensely engorged. There was a large blood clot in the stomach. Blood serum was oozing from the nostrils.

The speaker said he had been unable to find in the literature any reference to such a peculiar mucus cord as the one found in the ileum. The enormous quantity of air in the stomach and intestine was accounted for by the insufflations, the air having expanded somewhat probably under the heat of the body. The distention interfered with respiration and proved the immediate cause of death in the infant already asphyxiated. It had been stated by Delafield that distention of the stomach with aërated mucus might become a serious complication in bronchitis in infants. Possibly the emphysema was caused by the forcible insufflation, but this hardly seemed sufficient to explain it. Most writers on the diseases of children stated that the chief cause of interstitial emphysema was violent expiratory efforts with obstruction to the expired air. While there was no consolidation the compression of the lung from the abdominal distention produced atelectatic areas. The hemorrhages and venous congestions were due to the asphyxia, which was the manner of death.

Dr. Prudden said he saw this mucus cord, which resembled a tape-worm in many respects, although anyone would avoid confounding the two.

The Society then went into executive session.

Naughty Editors.—A Philadelphia contemporary says that a gentleman who entertained with a banquet the American Medical Editors' Association in San Francisco, is reported to be actively interested in a much advertised secret nostrum.

Death of a Lady Bicyclist.—The death of the lady cyclist from syncope after a bicycle ride is, of course, the text for many fraternal warnings, and advice to lady bicyclists to give up the enjoyment of an exercise in which it is feared they may indulge to excess. They are, of course, told by some that bicycling is unlady-like, if not unwomanly, and that women do not know how to practise the careful restraint in such matters to which men are accustomed. They may very well afford, however, to treat all this sage advice as at least superfluous. So far from being unsuited for woman, bicycling is an exercise in which they may indulge with perfect security, and generally with much advantage. We are persuaded that they are as little prone to excess in athletics as are the generality of men, and within reasonable bounds we should like to see cycling as generally practised by women as by men, and it would be greatly to the advantage of many cycling clubs and cycling resorts that the lady-like element should be more largely introduced.—*British Medical Journal.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE EXTRA MEETING OF THE MEDICO CHIRURGICAL SOCIETY—LAWRIE OF HYDERABAD ON CHLOROFORM—DISCUSSION OF HIS VIEWS—A MUNIFICENT ENDOWMENT OF SCIENCE—THE INSTITUTE OF PREVENTIVE MEDICINE—MR. A. BALFOUR, M.P., ON SCIENCE—THE COLLEGE OF SURGEONS ELECTION—SIR GEORGE HUMPHRY—THE APOTHECARIES COMPANY.—THREATENINGS OF CHOLERA—CIRCULAR OF LOCAL GOVERNMENT BOARD—HOSPITAL SUNDAY FUND—DISCONTENT OF SOME SUPPORTERS—THE CHELSEA HOSPITAL INQUIRY—BARONETCY FOR THE DUCHESS OF YORK'S ACCOUCHEUR—FELLOWS AND MEMBERS OF THE ROYAL COLLEGE OF SURGEONS.

LONDON, July 7, 1894.

THE extra meeting of the Royal Medico-Chirurgical Society which I announced as arranged for in my last, was held on Tuesday. The object being to enable Surgeon Lieutenant-Colonel Lawrie, while in London, to state his views on chloroform. These views will be familiar to your readers from the report of the Hyderabad commission, of which Dr. Lawrie is the father. It is therefore unnecessary to give an abstract of his communication to the Society, but the conclusions he submitted were: 1. That chloroform had no direct action on the heart. In support of this he explained an enlarged photograph from the fed animal in a cross-circulation experiment in which chloroform sent to the heart alone produced no effect whatever. 2. In a similar experiment chloroform sent to the brain alone produced its usual effects by acting on the brain centres. 3. He showed the difference from the same illustrations between taking respiration or pulse as a guide to the effect of chloroform when the respiration was regular. 4. Similar differences under the same conditions, but when respiration was irregular from vagus stimulation. 5. He exhibited a tracing to show that chloroform anæsthesia without respiratory complication was free from risk.

Looking at the discussion that has taken place on the Hyderabad commission Dr. Lawrie could not expect these conclusions to meet with unanimous assent, but he must be gratified with the amount of support he received at the Society and the great respect shown to his labors by even those who cannot endorse his views.

Drs. Gaskell and Shore both spoke. It is known that their experiments do not exactly coincide with Dr. Lawrie's. They admit that respiration fails first, but they think chloroform has also a direct action on the heart. In one of their cross-circulation experiments the respiration continued five minutes after the heart ceased to beat. Dr. Brunton suggested that peptones which had been used to prevent clotting of the blood, being poisonous, might account for some of the results, and held that it was certain that chloroform paralyzed the respiratory centre before affecting the heart. He speculated a little on the possibility that the increased consumption of meat of late years may have some relation to the increased fatality of chloroform, especially as strong, healthy men, on full diet, gave most trouble, and were more likely to have alkaloidal products circulating in the blood.

Mr. Horsley felt sure Dr. Lawrie was right as to most cases, and he exhibited a series of tracings on the screen to show the mode of death in bullet wounds of the brain, and said it was precisely similar in all cases of cerebral compression. Mr. Bailey said the pulse should be watched as well as the breathing. Dr. D. Buxton thought a considerable proportion of deaths were due to carelessness, and only a few to primary action on the heart, but he admitted that probably the secret of safety was to watch the breathing. Dr. D. Newman had seen two cases of cardiac failure, and in one of them the pulse stopped, although breathing continued and air entered the chest freely. He thought the respiratory centre more likely to fail than the heart. Dr. Hewitt also mentioned a case in which respiration continued though no pulse could be felt at the wrist, and he thought that we should be led into difficulties if we looked to the respiration alone in profound anæsthesia. Dr. Lazarus-Barlow exhibited a tracing taken directly from the heart of a curarized animal, to show that cardiac failure began with the commencement of inhalation, respiration failing later. Dr. Silk declared that an increased number of deaths had taken place since the Hyderabad report, and that though respiration should have primary attention the pulse must also be watched.

Dr. Lawrie in reply remarked that the sudden stoppage of the heart in the cases mentioned could only have been produced by stimulation of the vagus through the respiration—that the experiments of Dr. Lazarus-Barlow indicated some damage to the circulation in the lungs. He had found no difference in the effects of chloroform on Europeans and natives. In seven hundred cases the pulse had been carefully watched, but gave no indication. Finally, he said it is impossible to teach a careless man to give chloroform safely.

Mr. Mond has endowed scientific research in a munificent manner. He has bought the Earl of Albemarle's mansion, contiguous to the Royal Institution, and presented it to that body. Further, he proposes to meet the cost of converting it into a laboratory, and equipping it for chemical and physical research. He intends also to endow it with sufficient income for maintaining it and employing a skilled staff. This splendid addition to our scientific resources is to be called the Davy-Faraday Research Laboratory, and its establishment is expected to cost Mr. Mond some £100,000. The old country is not yet destitute of munificent donors.

The British Institute of Preventive Medicine is in a fair way of success. The site has been purchased and some important sums have been secured, *e.g.*, £10,000 from the Grocers' Company—one of the most liberal of the city companies; £20,000 from the Berridge trustees, and a further £25,000 is about to be handed over from the same source. The College of State Medicine will also hand over its plant and money to the Institute, in value above £4,000. Some of the investigations I have mentioned in previous letters were carried out for the Institute, and now that a suitable building is about to be erected the silly opposition of the antis to this undertaking may be diverted into other channels.

Mr. Arthur Balfour, who so rapidly rose to the highest position in Parliament, is a metaphysician of no slight attainments and a profound economist. Speaking last week at the Economic Association he touched on scientific investigations with a light but firm hand. He said the public had never yet mixed themselves up in these matters without spoiling the investigations and doing themselves a great deal of harm. When the public took up a question, party feeling—necessary in political affairs—was sure to come in and as sure to produce disastrous results. He instanced the question of vaccination, which the doctors thought they had settled on scientific principles, but on which a section of the public who had not studied it in the scientific spirit were determined that their feelings should override science. Not being a doctor he would not pronounce as an expert, but he had no doubt that if scientific questions were to be decided by universal suffrage, only harm could be done to this suffrage, while it would be absolute ruin to science. If science is wrong, he said, it could only be got right and turned into the direction of truth by giving it free play outside altogether the influence of popular forces. The idea that a section of the public had an opinion worth having on such subjects was to him absurd.

The elections at the Royal College of Surgeons took place on Thursday (5th).

Messrs. Howard Marsh and Reginald Harrison were re-elected, and the third vacancy was filled by the election of Mr. James Hardie, of Manchester. The provin-

cial Fellows have, therefore, again succeeded in placing one of their number on the Council.

Sir George Humphry has continued to improve, and is now able to take carriage exercise.

The apothecaries' company has issued a calendar, and an interesting document it is, showing that it has done good work for the profession in the past.

LONDON, July 21, 1894.

UNEASINESS is felt in many quarters at the recrudescence of cholera on the continent, which is becoming in some countries serious. About two hundred attacks a day in St. Petersburg, and outbreaks much nearer our shores are certainly enough to make sanitary authorities anxious. The local government board has issued a circular urging the utmost vigilance as to all suspicious cases and promising favorable considerations to any proposals to add diarrhœa to the list of notifiable diseases for the remainder of the current quarter, after which the danger may be considered over for this year. In former epidemics the disease has been more fatal in the second year of its invasion, and many are accordingly asking each other whether we are now in the second year, or whether the cases last year were only stray ones, brought by ships and infecting a few persons in communication with them. If so the present may prove to be the first year of an invasion should it pass our boundaries. If otherwise, and last year is to be reckoned as the first of an epidemic, the seeds, so to say, of the disease have been sown sufficiently broadcast to cause anxiety. Our sanitarians speak confidently of our preparedness, though they admit the existence of weak spots in our armor, and if once an epidemic gains a footing there are many inland towns and villages but ill prepared to meet it.

Above £42,000 has already been received for the Hospital Sunday fund, and this is nearly £3,000 more than last year's collection, while other sums have yet to come in. Much credit is due to the *Lancet* for the spirited way in which it has contributed to the success of the fund. I am, therefore, rather sorry to notice that your powerful contemporary seems inclined to consider the management of the fund immaculate and endeavors to account for the discontent that has been evinced in a manner that facts will scarcely support. "Bad management" is the excuse put forward for refusing to include some institutions in the distribution. The truth is, in some cases, the so unfairly stigmatized management is the expense of each patient, especially in dispensaries and out-patient special institutions. These expenses consist largely in the use of drugs and appliances which the specialists say cure the patients and which, being costly, are not much used at great hospitals where patients are hurriedly got through in a few seconds each. I know that in some cases this contention is not without foundation. The supporters of the fund are apt to be angry too, when a sermon is preached on behalf of some institution selected by the preacher or his people, and when boxes are distributed to collect for such charity. Now it is really the management of the fund that has led to this action. The large hospitals, which, of course have the first claim, have their friends on the committee and very scant justice has been done to small, especially special hospitals. The prejudice against specialism has been fostered by the fund committee and their officials do not hesitate to express it. What more natural than that a preacher interested in a special hospital, knowing its working, and perhaps taking part in its management, should say, if you refuse to include this charity in your list I will give my collection to it alone? This kind of thing will increase if lay officials are to reflect the prejudices of a party. In the interest of hospitals I deprecate such divisions, although I am not quite sure that they may not eventually prevail and do good. For, after all, what is £40,000 for the rich metropolis to raise?

The committee appointed to investigate the charges brought by the medical officer of health (Dr. Louis Parkes) against the Chelsea Hospital for Women has issued its report. They say it was the duty of Dr. Parkes to notice the matter, but they do not understand why he omitted to inform the vestry that at the time he presented his report the hospital had been empty for three weeks, and that he had received a letter from the secretary stating that the works would be carried out as soon as possible and completed before patients were again admitted. They further state their opinion that a large number of the deaths were due to septicæmia, and that septic temperatures did not prevail in the practice of every member of the staff. This seems to me rather a lame conclusion or else an insinuation, unjustifiable unless supported by facts, in which case it should have been plainly stated. The medical officer of health attributed the mortality to insanitary conditions. The committee of inquiry offers no conclusion on this point, which is a vital one.

The occasion of the birth of a son to the Duke of York has been taken by the Queen to confer a baronetcy on the physician-accoucheur—Dr. John Williams—who has also attended other members of the royal family, and is one of our most eminent obstetricians.

The fellows of the College of Surgeons have held their meeting and congratulated the council on its concessions. The two societies almost approached each other and the sooner their rivalry disappears the better. There was no room for the latest of the two, but the matter only concerns the exclusive fellows. The council has issued a series of regulations for the meetings of members. They are admirably adapted to prevent these members from doing anything except at the council's bidding.

The constitution of the college needs radical reform.

The slight changes granted to the fellows induces them to ask to have them embodied in a new charter. If the members do not obtain some recognition in any such proposed instrument, they should combine to oppose it, and the privy council would no doubt accord them a hearing before recommending the grant of the charter.

THE PATENT MEDICINE SCOURGE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The sad death of the young woman, Natalie D——, which recently occurred in Montreal, should serve as a warning to the public, and stimulate the medical profession to enter a vigorous protest against the patent medicine scourge which is now raging throughout this continent. At the inquest, held on the body of the deceased, the coroner read a few letters from some women asking for these pills which the deceased had taken for the purpose of procuring abortion. He stated that he produced these letters to show what great evils such articles could do.

Your readers are only too well aware that the advertising columns of almost every daily and weekly newspaper —and also of magazines, almanacs, and pamphlets—contain glowing descriptions of the "miracles" which have been performed by Dr. So-and so's pills, or some one else's marvellous medical "discovery." Surely it is time that the medical profession stepped in, and, *una voce*, urged the proper authorities to place more stringent regulations on the sale of dangerous and poisonous preparations. We have only to glance through the advertising columns of reputable publications, and we shall find the narrative of some unfortunate sufferer, who pathetically relates how he or she has been snatched from the very jaws of death, after having unsuccessfully consulted (?) all "the leading physicians" in that particular section of the country. As a rule, a crude portrait of some vigorous looking individual adorns the account in order to render the narrative the more attractive, and the more effectually to catch the public eye. I believe it was the late Lord Chief Justice Coleridge (England), who stated that a country was composed of so many millions of people principally consisting of persons possessing a naturally dwarfed intelligence; and no more satisfactory

evidence of this can be afforded than the fact that a patent medicine speculator has only to advertise a new and startling "discovery," and he will immediately receive numerous testimonials extolling his remedy, and thanking God that such a benefactor to the human race has suddenly sprung into existence. It is surprising to find how large a number of persons consult physicians nowadays who frankly confess that they have been habitually using a certain much-lauded pill, or some other compound, which has probably been purchased at a neighboring general store; and only as a final resort have the purchasers been at length compelled to seek medical advice; nor can it be disputed that thousands of women annually imperil their lives by employing dangerous patent medicines for escaping the consequences of marriage, or to avert the trouble arising from illicit sexual union.

The time has arrived when both the medical profession and the public should be protected from a traffic which is hurtful to the community and is slowly undermining the practices of qualified medical men. It is almost unnecessary to point out that no case can be successfully treated unless the whole history, symptoms, and environment of that particular case be properly studied and understood. Furthermore it is a lamentable fact that, in all likelihood, many lives are lost which may be directly attributable to the reckless use of some obscure concoction entirely unsuitable to the disease for which it is administered. It is readily conceivable that, among the many thousands who purchase popular nostrums, and rely solely upon their supposed curative powers, not a few go from bad to worse; and only when too late do they hasten to seek sound, practical, and judicious counsel from an intelligent medical practitioner.

R. H. Phillimore, M.D.

Cookshire, Quebec, Canada,
July 23, 1894.

POLITZER'S OPINION ON MEDICAL EDUCATION IN AMERICA.

To the Editor of the Medical Record.

Sir: The article in a recent issue under the heading "Is there a Need for more Medical Schools?" recalls to mind an interesting lecture which was delivered before the Medical Society of Vienna, by Professor Politzer, in March last.

The meeting was open to all physicians, and many Americans, including myself, took advantage of it.

Professor Politzer, it seems, was sent by the Austrian Government to the United States to investigate the medical institutions, hospitals, and surgical and medical apparatuses.

What he said regarding our medical institutions was certainly displeasing to the Americans; nevertheless, it was true. He said that the United States, with a population of sixty or sixty-five millions, had one hundred and forty-eight medical schools, while the total number of medical schools in Austria and Germany together was twenty nine. Russia, with a population of about one hundred millions, had nine medical schools.

He also mentioned other European countries with a similar ratio. Regarding the formation of medical colleges in the United States, he said that all that was required to organize a college was a few doctors and an appeal to the Legislature for a charter, which was always granted. This remark was greeted with considerable laughter.

He said that almost every city of any considerable size had one college, some two—and that new ones were springing up every day—and that occasionally one dropped out of existence. Some of our schools gave degrees in two years, but he was glad to find that some of the better schools had increased the time to four years. In Austria and Germany a five-and-a-half years' course is required. Our hospitals and surgical instruments he praised very highly.

Oliver A. Blumenthal, M.D.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 4, 1894.

	Cases.	Deaths.
Tuberculosis	85	91
Typhoid fever	21	7
Scarlet fever	40	5
Cerebro-spinal meningitis	2	7
Measles	27	5
Diphtheria	146	37
Small-pox	6	1

The Late President of the French Republic and his Surgeons.—The *Progrès Médical* of June 30th gives, on the authority of Professor Poncet, of Lyons, the following details as to the surgical treatment pursued in the case of the late President of the French Republic. The wound was inflicted at a quarter past nine in the evening, and M. Poncet, who was at once summoned, found M. Carnot in a state of collapse, and with the aspect of one at the point of death. Tearing open the shirt and underclothing, M. Poncet found to the right of the line a alba, about three centimetres from the ensiform cartilage, parallel to the edge of the false ribs, a wound from twenty to twenty-five millimetres in length, from which black blood was oozing. He contented himself in the first instance with applying a handkerchief lightly to the wound, and with the view of preventing fatal syncope, he placed the President as nearly in a horizontal position as the carriage would allow, and strove to rouse him by speaking to him and occasionally tapping his face with his fingers. On the way to the Prefecture, distant about one kilometre, the President, who was unconscious, retched two or three times, but did not vomit. On arriving at the Prefecture he was laid on the bed with his head low, and while waiting for aseptic instruments M. Poncet applied iced compresses to the abdomen. A few minutes later, considering surgical interference to be urgently necessary, he, with the help of Drs. Masson, Monnoyer, Demandre, and Lépine, and in the presence of Professor Gailleton, Mayor of Lyons, and Drs. Kelsch, Albert, Fabre, and Rebatel, performed a local laparotomy, no anæsthetic being given on account of the collapsed state of the patient. An incision of ten to twelve centimetres was made and progressively extended as the necessity arose; this incision was a prolongation of the wound made by the assassin's dagger. A considerable quantity of blood escaped, and M. Poncet, introducing his left forefinger into the depth of the wound, was able clearly to make out on the anterior surface of the left lobe of the liver, near the suspensory ligament, a wound of the same dimensions as that in the skin. Separating the edges of the wound with forceps he saw, a little above the costal arch, the wound in the liver, into which the forefinger penetrated to a depth of two to three centimetres. Such rapid examination as was possible failed to reveal any lesion of the gall-bladder, stomach, intestine, etc. At this stage of the operation Professor Ollier arrived, and M. Poncet having shown him the nature of the wound, and the impossibility of suturing the wound in the liver—a procedure, moreover, which appeared to be useless in view of the fact that the bleeding could at once be stopped by pressure—it was agreed, having regard to the collapsed state of the patient, simply to plug the wound. Some fibres of the rectus, which interfered with the manipulations, were divided by another incision of five to six centimetres inward toward the middle line. The wound was plugged with iodoform gauze; then compresses of sterilized gauze were applied and fixed in place by a body bandage drawn moderately tight, while an assistant kept up slight pressure with his hand. At the beginning of the operation, when the first

incision was made, the President recovered consciousness, and said in a clear voice, "Oh! doctor, how you hurt me." From that time he seemed to recover strength a little and answered questions with perfect distinctness. He was given small pieces of ice and a little iced champagne, and two subcutaneous injections of a gramme of ether were administered at an interval of twenty to thirty minutes. The President complained of a certain difficulty in breathing and of pain in the stomach and loins. At half-past twelve his voice was still resonant, and he expressed his gratitude for what was being done for him. A minute or two later there was some return of the hemorrhage, and convulsive movements occurred which caused the intestine to show a tendency to protrude through the wound. At thirty-eight minutes past twelve he died.—*British Medical Journal.*

The Anti diphtherin of Klebs.—Dr. Oscar Vulpius applies the liquid with a long-handled camel's-hair brush, which is readily managed, first to the tonsils and soft palate, and, after thorough cleansing, to the pharynx. With restless children one must be content with imperfect treatment, and even with one application; even the liquid may be expelled by vomiting before, indeed, it can reach the membrane. The results as noted include a marked subsidence of the fever; the membrane may remain entirely unchanged during the treatment, nor, indeed, does this treatment prevent the tendency of the process to invade the trachea and bronchial tubes, consequently it has no influence in preventing croup. However, as it is important that the remedy shall be brought into close contact with the diseased surface, it should be again applied as soon as the membrane is coughed up. In his series of cases, nineteen in number, the percentage of deaths was 52.6; omitting one case of the rare accident, late secondary hemorrhage after tracheotomy, the rate falls to fifty per cent. Whether with an improved anti-diphtherin, or with possibly a combination with this of a diplococcus poison, better results may be obtained, the future only will determine.—*Deutsche medicinische Wochenschrift*, 1894, No. 6, S. 127.

Thyroid Feeding in Myxœdema.—Dr. S. J. Meltzer reports in the *New Yorker medicinische Monatsschrift*, No. 4, 1894, an interesting case of myxœdema in a woman, thirty-seven years of age, successfully treated with powdered thyroid extract. At the time of the report the improvement, as shown by photographs, was most marked, and there was every reason to anticipate a complete recovery.

Some Ancient Theses for the Degree of M.D. Paris.—M. Jules Roger, in his interesting book, "Médecins, Chirurgiens, et Barbiers," gives the following list of subjects of theses sustained in old times before this faculty: 1572. La nécessité de la mort est elle innée? 1576. Le fœtus, ressemble-t-il plus à la mère qu'au père? 1589. L'air est il plus nécessaire que la nourriture et la boisson? 1622 L'eau est-elle plus salutaire que le vin? 1639. Doit-on saigner une jeune fille folle d'amour? 1643. S'enivrer une fois par mois est-il salutaire? 1646. La femme est-elle un ouvrage imparfait de la nature? 1662. Le libertinage amène-t-il la calvitie? 1668. Les Pari siens sont ils sujets à la toux quand souffle le vent du nord? 1714. Quel est le plus salutaire, de l'eau pure, du vin pur, ou du vin mélangé d'eau? 1745. Les littérateurs doivent-ils se marier? The *naïveté* of the preceding questions is charming, but he must have been a courageous man who, even in 1646, could gravely ask the question, "Is woman an imperfect work of nature?"—*British Medical Journal.*

Cancer Houses.—Several correspondents of the *British Medical Journal* have reported instances in which the successive occupants of certain houses have died of cancer. In many cases there was no history of heredity, and often there was no relationship between the persons successively attacked with the disease.

A Convivial Occasion.—The doctors of the Gironde dined together on Sunday, June 17th, at Pauillac, and the banquet was, according to the *Echo*, moistened by 218 *crus* and 340 varieties of wine. The *carte* was in twelve pages, setting forth in elegant typography the virtues of the most reputed *crus* and the most famous years. There were 1,400 bottles to 170 doctors. This goes ahead of the annual banquets of the Maine State Medical Society.

Lucky Numbers and Lucky Medical Students.—Two French medical students, M. Gustave Lefilliatre and M. Georges Labey, had recently a letter from a solicitor named Leger, of Marines, Seine-et-Oise, stating that the late Dr. Dubois, a medical man at Chars, had left a will by which he bequeathed all his surgical and medical appliances, free of legacy duty, to two students obtaining their degree at the examination next after the decease of the testator. The two students selected were to be those who came out No. 14 and No. 84 in the list. At first it was thought the letter was a hoax, but the two young men went to the place indicated, and were there duly presented with an exceptionally fine collection of instruments and accessories of all kinds for division between them. They learned that their being specially chosen was due to the fact that the deceased doctor had twice passed an examination, and that he had on those occasions been No. 14 and No. 84 on the lists.

Professor Gussenbauer, the newly appointed incumbent of the Chair of Surgery in the University of Vienna has been elected President of the Twenty-fourth Congress of the German Society of Surgery to be held in 1895.

Profitable Quackery in Russia.—The police in Kieff recently made a domiciliary visit to the proprietor of some "magic pills," a former blacksmith in Warsaw. In searching his effects they found 3,782 letters containing orders for pills, with enclosures amounting in all to over $5,000. The letters were from persons of all classes, including priests, apothecaries, and government officials.

Sanitation Sunday.—We have labor day and hospital Sunday, and other interesting memorial occasions, but the English churchman goes ahead of the record and proposes a "Sanitary Sunday." The Church Sanitary Association suggests that the seventh Sunday after Trinity be known as Sanitation Sunday, because the gospel for this day contains the record of Christ's disciples distributing wholesome food to those who were already in the enjoyment of fresh air, pure water, and abundant light, thereby indicating the Divine will that man shall enjoy fulness "as well for the body as the soul."

Instruction in Dentistry in France.—In the French Budget for 1895 is an appropriation of $15,000 to provide for the organization of chairs of dental surgery in several of the medical schools of the country.

Contract Medical Practice.—The London (Ont.) Medical Society has been deliberating on the question of contract or lodge practice, and offers the following suggestions looking to its abolition or restriction: "1. Apply for legislative authority to prohibit contract practice. With the prevailing contract rates at $1.00 and $1.50 per member, this prohibition might be shown to be in the interest of the public as well as the profession, inasmuch as indifferent service is a natural result of inadequate remuneration; or, 2. Apply for legislative power to fix a minimum tariff of contract rates. A Toronto medical journal, in December, 1893, claims, on the authority of a distinguished actuary, that the proper remuneration for contract practice in Canada is $4.00 a year per member; or, 3. Apply to the Legislature for power to frame and enforce a code of medical ethics, with a view to control the evil; or, 4. Address an appeal to every registered practitioner to discountenance the system. The influence of such an appeal coming from the representative body of the profession would tend to bring the practice into disrepute."

ANATOMY OF CLUB-FOOT.

By FRANK HARTLEY, M.D.,

NEW YORK.

In the *Annals of Surgery* of March, 1894, will be found an article written by the author of this paper, entitled "The Operative Treatment of Club foot," in which the records of twenty six cases operated upon from 1886 to 1893 were detailed. It was recommended in that article that in the minor cases, before the thirtieth month of life, mechanical fixation with or without tenotomies and fasciotomies were sufficient. After that age in the child, tenotomies and fasciotomies were to be combined with a talus extirpation in all cases where the equinus was the prominent deformity and the varus slight, provided the tenotomies and fasciotomies had not completely reduced the deformity.

In those cases where, in addition to the equinus, the varus was marked, a limited cuneiform osteotomy involving only the processus anterior calcanei and the articular surface of the cuboid, was to be added, if necessary.

In the adult, after the usual tenotomies and fasciotomies, a cuneiform osteotomy involving parts of the os calcis, cuboid, neck of talus and scaphoid, was recommended if the equinus was relieved after tenotomy. If the equinus was not thus relieved, either a partial or total talus extirpation was to be combined with a cuneiform osteotomy at Chopart's joint. It was also stated that the severest forms of club foot (inveterate cases) were only cured by both of these procedures. To-night I wish to give the results of a dissection of two feet which represent perfectly the highest degree of this deformity, and, in my opinion, substantiate the view taken in so far as the inveterate cases are concerned.

This specimen represents a club foot of congenital origin and of twenty-two years' standing, in which the rotation inward of the leg is marked, and the position of extreme supinative plantar flexion and adduction is present in the foot.

The movements of the joint surfaces were all limited. In the talo-crural joint, the movement was confined to a simple gliding in which the antero-posterior was less marked than the lateral motion. In the talo-calcanean joint scarcely any movement was appreciated. In Chopart's joint a movement corresponding to flexion and extension was more marked than in the other joints. In none of the joints was there more than a gliding movement in one or more planes. These movements produced only a limited change in the relations of the different bones of the foot to one another or to the leg. The bursæ found consisted: 1, Of a large multilocular cavity covering bearing points of pressure which are sure to be the anterior process of the calcaneus and the dorso lateral surface of the cuboideus; 2, of a smaller multilocular bursa covering the neck of the talus and the lower portion of the external malleolus. The ligaments were not peculiar nor of interest. On the external border of the foot a large amount of fibrous tissue was present, and many new bands of this tissue seemed to be added to the normal ligaments. Upon the inner border and sole of the foot the fibrous tissue was not so extensively developed, although the plantar ligaments were well marked, thick, and out of all proportion relatively to the muscular tissue. The anterior annular ligament was well developed, thick, and strong. The external annular ligament consisted of a firm broad band covering the peroneal tendons as they passed to the posterior surface of the calcaneus. The internal annular ligament was well marked but very short, on account of the position of the foot. The muscles, which in the leg and foot show a marked atrophy with fatty and connective-tissue transformation, had the following relations, which were peculiar:

1. The tibialis anticus passed over the lower third of the tibia, from without inward, to the inner surface of the internal malleolus, whence it descended to its insertion.

2. The extensor proprius pollicis passed through a separate compartment of the annular ligament over the

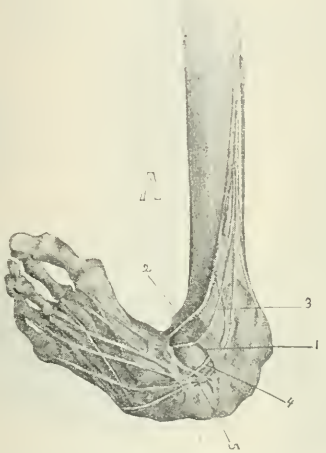

FIG. 1.—ANTERIOR VIEW: 1, Anterior annular ligament; 2, tibialis anticus; 3, extensor hallucis; 4, extensor longus digitorum; 5, peroneus tertius.

inner surface of the internal malleolus, close to and in front of the tibialis anticus. It divided into two tendons which were inserted into the second phalanx.

3. The extensor longus digitorum passed over the outer third of the anterior surface of the tibia, in a groove bounded by two well marked prominences. It was covered by the annular ligament. It divided into four tendons, which passed obliquely inward over the heads of the first and second metatarsal bones to the four toes.

4. The peroneus tertius passed obliquely outward to the base of the fifth metatarsal bone over the cuneiform bones.

5. The extensor brevis digitorum is scarcely observable except for its tendons.

6. The peroneus longus and brevis passed beneath a strong and narrow band of fascia, extending from the external malleus to the calcaneus, and representing the external annular ligament, around the external and posterior surface of the calcaneus (inferior surface) to their

insertions. The former did not touch the cuboid bone. It passed above the level of the anterior process of the calcaneus obliquely, directed from without downward and inward. The latter, after passing over the anterior process of the calcaneus, descended upon the lateral border of the cuboid bone to its insertion.

7. The tibialis posticus passed to the inner side of the internal malleolus, its posterior border, beneath it, and to its insertions.

8. The flexor longus digitorum passed to the outer side of the tibialis posticus, beneath the internal malleolus, to its insertion.

9. The flexor longus pollicis passed through a well-marked groove in the tibia, external to the flexor longus digitorum, beneath the internal malleolus, and was lost in the muscles of the foot.

The relations of the bones of the foot to one another

FIG. 2.—LATERAL VIEW: 1, External lateral ligament; 2, peroneus longus; 3, peroneus brevis; 4, tendo Achillis.

FIG. 3.—POSTERIOR VIEW: 1, Tendo Achillis; 2, peroneus longus; 3, peroneus brevis; 4, tibialis posticus and flexor longus digitorum; 5, flexor longus hallucis; 6, abductor minimi digiti.

and to those of the leg, were in general as follows: Most striking in this respect was the angle formed by the bones of the leg and the calcaneus. The position of the calcaneus was one of marked plantar flexion. Its long axis formed, with the articular surface of the tibia, an angle of 80°. If we consider the mid-position of the foot (talus or calcaneus) to the leg to be one of a right angle (90°), and allow 39° for the extreme of normal dorsal or plantar flexion, we have here 41° of a forced plantar flexion of the foot. Less striking, but no less important, is the supination of the calcaneus, which, when measured, shows an increase of 50° over the normal position of adult bone. There is a slight adduction of the calcaneus present, which amounted to about 10°.

On account of the forced plantar flexion, the supination and adduction, the superior articular surfaces are altered in their relative position to the talus, and to the tibia and fibula. Besides the articular surface for the talus, we have upon this surface, just in front of the tuberosity, nearthroses for both the tibia and fibula. That for the former is continuous with the external third of the articular surface

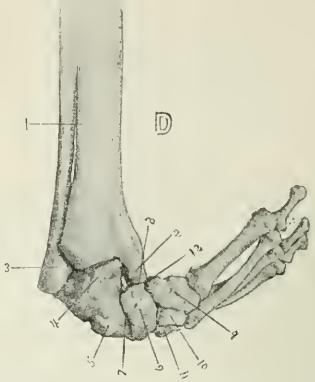

FIG. 4.—ANTERIOR VIEW: 1, Tibia; 2, internal malleolus with nearthrosis between it and scaphoid and internal cuneiform; 3, external malleolus articulation with talus; 4, talus—body; 5, neck of talus—inward angle, downward angle, 90°; 6, navicular bone; 7, talo-navicular articulation, situated entirely upon the inner side of neck; 8, nearthrosis between internal malleolus and navicular bone; 9, internal cuneiform; 10, middle cuneiform; 11, external cuneiform. 12, nearthrosis between internal cuneiform and internal malleolus.

for the talus, and is situated upon the superior surface (really internal). That for the latter is situated upon the external surface (really superior).

The processus anterior of the calcaneus is large and prominent. It sustains the greater portion of the weight

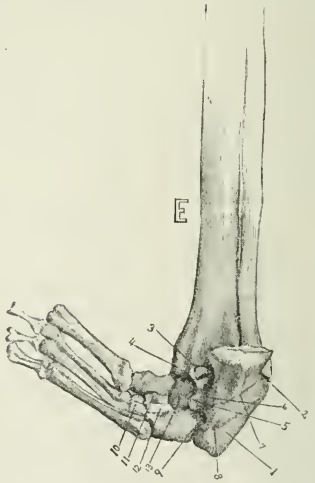

FIG. 5.—POSTERIOR VIEW: 1, Calcaneus; 2, nearthrosis between external malleolus and calcaneus just in front of the tuberosity and internal to nearthrosis between calcaneus and external malleolus, concealed from view here, is the nearthrosis between the tibia and calcaneus; 3, talus, all that can be seen from this view; 4, internal malleolus, articulating with the talus but with the navicular and internal cuneiform by nearthrosis; 5, sustentaculum tali, maintaining articulations by nearthrosis with the navicular bone; 6, internal surface of calcaneus; 7, 8, mark the relations of peroneus longus and brevis; 9, articulations of cuboid with inner surface of sustentaculum tali; 10, 11, 12, cuneiform bones; 13, navicular bone.

of the body. Situated upon the internal surface of the neck of the calcaneus is the articulation for the cuboid.

The talus is situated in the angle formed by the bones of the leg and the calcaneus. Its superior surface articulates with the tibia, and is external so far posterior as to

be continuous with the inferior articular surface in its outer half, and only separated from the internal half of the same surface by a 5 mm. strip of non-articular bone.

The shape of the body is triangular with the apex posterior, and with the superior and inferior surfaces looking respectively upward and downward and backward.

The neck of the talus forms with the body an angle of 45° for the inward displacement, and of 90° for the downward displacement.

The outer angle of the neck is less prominent than the internal. Upon the internal surface of the neck is an oval facet for articulation with the navicular bone, the long axis of which is placed at an angle of 45° to the long axis of the neck.

The navicular bone articulates with the neck of the talus only in the external portion of its posterior surface, while the internal portion of the same surface is non-articular and is bent sharply upon the outer segment.

The long axis of the navicular bone (*i.e.*, transverse) is nearly parallel with that of the neck of the talus.

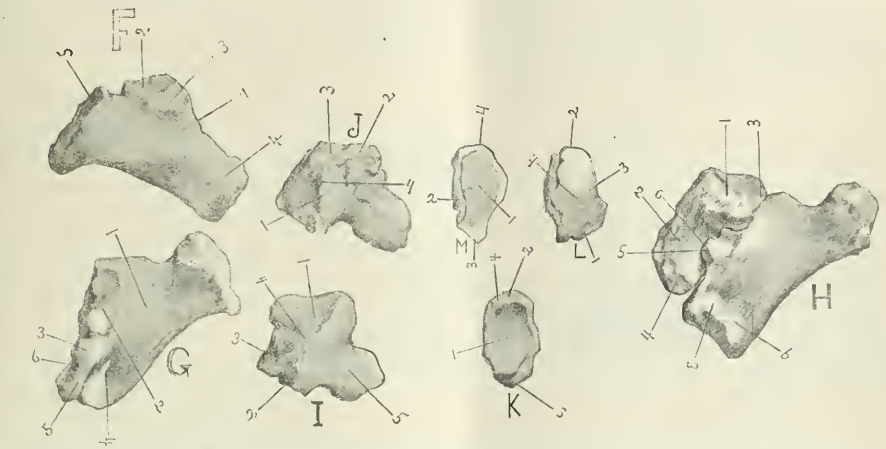

FIG. 6.—F. CALCANEUS.—1, External surface; 2, nearthrosis for external malleolus, just internal to it is the nearthrosis for tibia (concealed here); 3, articular surface (external) for talus, the posterior portion of this surface articulates with the tibia; 4, processus anterior calcanei; 5, tuberosity. G. 1, Internal surface; 2, internal portion of articulation for the talus, the superior border of which is continuous with the surface seen F 3; 3, sustentaculum tali; 4, articulation for cuboid; 5, marked ridge of bone continuous with the sustentaculum overhanging and articulating with the cuboid at posterior internal angle; 6, non articular superior surface of neck, covered by neck of talus.

H. TALUS AND CALCANEUS—INTERNAL SURFACES.—1, Body of talus triangular in shape; 2, neck of talus; 3, point at which superior and inferior surfaces are continuous; 4, articulation for navicular bone; 5, sustentaculum tali; 7, nearthrosis with neck of talus; 8, 9, articulations for cuboid.

I. TALUS—ANTERIOR AND SUPERIOR VIEW.—1, Super-articular surface for tibia; 2, articular surface for fibula; 3, non-articular surface for fibrous bands between two articular surfaces of the fibula uniting the fibula and talus; 4, body of talus; 5, neck of talus ninety degrees downward, forty-five degrees inward.

J. INFERIOR AND EXTERNAL VIEW.—1, Inferior articular surface for calcaneus; 2, articular surface for fibula; 3, non-articular surface for fibrous bands to fibula; 4, tibia articular surface.

K. NAVICULAR BONE—POSTERIOR VIEW: 1, Oval articular surface for articulation with inner surface of the neck of the talus; 2, internal border; 3, external border; 4, second tuberosity, place where it ought to be.

L. SUPERIOR VIEW.—1, External border; 2, internal border; 3, posterior border; 4, superior surface.

M. ANTERIOR AND INFERIOR VIEW.—1, Anterior surface of cuneiform bone; 2, inferior surface very narrow as compared with the superior surface in L. 4; 3, internal border; 4, external border.

This bone presents two nearthroses. One for the anterior surface of the sustentaculum tali; the other for the internal malleolus at its anterior and inferior angle.

The superior surface (anterior) is broad. The inferior is narrow. The external is narrower than the internal. There is no tuberosity present, nor does this bone articulate with the cuboid. The transverse axis forms with the transverse axis of the cuboid an angle of ninety degrees.

The cuboid bone articulates with the anterior process (*i.e.*, neck) of the calcaneus upon its internal surface, in such a manner that the weight of the body is in part sustained by the dorso lateral surface. There is no sulcus for the peroneus longus tendon, nor is the tuberosity present. The three cuneiform bones articulate with the navicular and cuboid in the angle formed by them. Their position is one of marked supination, adduction, and approximation of the inner and outer bones toward the plantar surface. This approximation diminishes gradually as one passes beyond to the metatarsal and phalangeal bones. Considering these bones more carefully, we find that the talus is made up of a body and a neck. The body is triangular in shape, with its apex posteriorly. The superior articular surface looks directly upward, and is continuous along the outer half with the inferior articular surface at the posterior border, while along the inner half this surface is separated from the inferior by a 5 mm. strip of non-articular bone. The inferior articular surface is directed downward and backward. The outer half is convex, and is directed outward. The inner half is concave, and is directed slightly inward. The facet for the internal malleolus situated nearer the anterior than the posterior surface of the body is broad, flat, and continuous with the superior articular surface. The facet for the external malleolus, situated near the posterior surface of the body, is narrow and is separated from the superior articular surface by a strip of non-articular bone. Just in front of the inferior articular surface is a very small articular facet for the anterior and superior surface of the sustentaculum tali. Upon the inner side of the neck of the talus is situated the articular facet for the navicular bone. The facet is oval in shape, and its long axis forms with the long axis of the neck an angle of forty-five degrees. The outer and anterior angle of the neck is much less prominent than the internal and anterior angle. It seems to be cut away. It is more rounded. The neck itself is somewhat flattened from above downward, and is rounded from side to side. The long axis of the neck forms with the antero-posterior axis of the body an angle of ninety degrees and with the transverse axis an angle of forty-five degrees.

Calcaneus: The position of this bone is first one of nearly full extension (plantar flexion). It forms with the tibia an angle of eighty degrees. It is also supinated sixty degrees, so that the nearthrosis for the fibula is situated upon the superior and external border, and that for the talus upon the inner surface adjoining the nearthrosis for the fibula. The bone is also adducted ten degrees.

Upon the superior surface we have four articular surfaces for the talus, tibia, and fibula. In the position in which the bone articulates these surfaces look upward in general. The articulation for the fibula looks upward,

outward, and slightly forward. Just in front of the tuberosity is also a plane articular surface looking upward and inward, for articulation with the outer third of the posterior border of the tibia. This surface is continuous with the outer portion of the articular surface for the talus. These two surfaces are nearthroses. Anterior and internal to them is the articulation for the talus, which is inclined outward for the outer half, inward for the inner half. It is concavo convex, with its long axis from without downward, forward, and inward. It extends so far forward as to be closely applied to the articulation for the cuboid. The sustentaculum tali is rudimentary, placed at a very low level upon the inner side of the bone, and articulates with the talus and navicular bone. The processus anterior is enlarged both in heighth and breadth. The body and neck, including the processus anterior, present a marked concavity upon the internal surface, which is increased in appearance by the enlarged tuber calcanei and anterior process.

The articular surface for the cuboid is entirely upon the inner side of the processus anterior, with its long axis at right angles to that of the calcaneus. This surface is oval in shape and is composed of two portions: The lower for articulation with post and external angle of the cuboid; the upper, which is situated just beneath and anterior to the sustentaculum tali, for articulation with the posterior and internal angle of the cuboid.

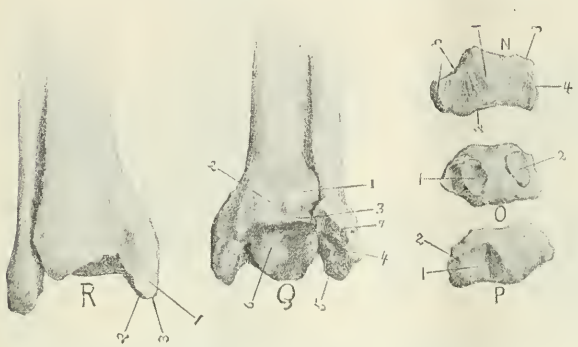

Fig. 7.—N. Cuboid.—1, Inferior surface; 2, interior border; 3, exterior border; 4, anterior surface; 5, articulation with calcaneus.

O. Anterior and Internal Surface.—1, Anterior surface; 2, internal surface with articulum for cuneiform. P.—1, Posterior surface composed of two surfaces, the one external or inferior marked for the calcaneus, the other, marked 2, at the posterior internal angle for calcaneus insertion of sustentaculum tali.

Q. Tibia and Fibula, Posterior View.—1, Groove marked for tibialis posterior and flexor longus digitorum; 2, groove for flexor longus pollicis; 3, articular surface for calcaneus; non-articular surface for fibrous bands attaching the fibula to calcaneus and talus; 6, posterior border of inferior tibial articular surface with articular surface for calcaneus; 7, articular nearthroses between.

R. Fibular Calcaneus—Anterior of Same.—1, Internal malleolus; 2, facet for articulation with navicular bone; 3, outer border of facet for articulation with cuneiform bone.

The internal border is narrower from above downward and longer from before backward than is usually the case. The tuberosity is wanting.

The anterior and posterior articular surfaces approach one another inferiorly. The posterior surface is concave and encroaches upon the external aspect of the bone, leaving a surface upon the inner posterior (posterior surface) free from cartilage. The cuneiform articular surfaces (anterior surface), besides being inclined inferiorly, are slightly displaced toward the external border. The bone is therefore more triangular in shape in two directions, *i.e.*, toward the planta pedis and the external border. There is no articulation with the cuboid bone. The long axis of the navicular bone is parallel to the long axis of the neck of talus. The nearthroses present exist between the internal border and the malleolus, between the sustentaculum tali and the inferior surface near the posterior border, and with the talus at the junction of its body and neck.

The cuboid bone is more quadrilateral than is normally the case. In new bone and in the adult cuboid, between the outer and inner border is respectively fifty per cent. and fifty seven per cent. In our club foot, however, this relation is raised to sixty six per cent., which is in part due to the lessened oblique position of anterior articular surface. This articular surface forms with the external border in the new born cuboid an angle of 72°, in the adult 79°. In our specimen it is 82°. The tuberosity of the cuboid is wanting, so that the height of the bone, especially at its posterior border, seems deficient. There is no articular surface for the navicular bone.

The posterior articular surface occupies more of the external surface than usual. This concavo convex looks backward and slightly outward, and is continuous with a nearthrosis upon the posterior and internal angle for articulation with the calcaneus just beneath and anterior to the sustentaculum tali.

The articular surface for the external cuneiform bone is well marked, occupying nearly one fourth of the inner side. It is raised above the surrounding surface with its articular face directed downward and backward, but in the articulated bone backward and upward.

The cuneiform bones are arranged rather behind than alongside one another. Their posterior surfaces are obliquely inclined, so that they look backward and upward, *i e.*, the lower border projects further backward than the upper border. Otherwise these bones present few changes of importance.

In the metatarsal bones the rotation of the diaphysis inward 90°, and greater development of the posterior surface upon the internal than posterior surface, are the only noticeable features.

The tibia and the fibula are rotated inward about their long axis. The malleolus externus is anterior to the malleolus internus. The transverse axis of the talo crural joint is from in front and externally to behind and internally; with the transverse axis of the body these axes form an angle of 30°.

Upon the fibular end, two articular surfaces are found, one for the talus and one for the calcaneus (a nearthrosis). These are separated by a non articular surface. Upon the tibial end three articular surfaces are found, one for the talus, one for the scaphoid, and one for the internal cunei form. The two latter are nearthroses.

In the club foot of the new-born, the neck of the talus is not only increased in length, but its downward and inward inclination is respectively 45° and 65°—against 15° and 45° in the normal newborn talus. This inclination of the neck accounts for the plantar flexion, according to Hueter.

Kocher, however, does not entirely agree with him in this view, since the talo-crural joint is in plantar flexion, as shown by the displacement of the superior articular surface backward and the meniscus found at the posterior border of this joint.[1]

The angle between the axis of the leg and the talus in calcaneus was one hundred and fifty degrees, as found by Kocher in the club-foot of a year old child. Plantar flexion is possible to one hundred and thirty degrees. This leaves twenty degrees of forced flexion in this case. In our specimen there is an angle of one hundred and seventy degrees present, so that we have forty-one degrees for a forced plantar flexion.

The articular surface for the navicular bone is entirely upon the inner side of the neck, oval in shape, with its long axis midway between the horizontal and vertical planes. In severe cases, the shape of this articular surface is rounded and its long axis is vertical. In our case this articulation has its long axis midway between a vertical and horizontal plane.

In the two cases examined by Kocher a great difference existed in the form of the neck. In the one year-old club foot the neck was abnormally long. In the

[1] Dissection by Kocher.

new-born club-foot the neck was only lengthened upon the outer side, in so far as the anterior end of the navicular articulation begins on the mesial side, while it is shortened upon the mesial side by the displacement of the articular surface. This difference in the length of the neck and the position of the talo-navicular facet is explained by Kocher as follows: "If in utero the pressure continues till birth, the growth of the neck is hindered and the anomaly consists in the displacement of the articular surface." After birth an unhindered growth takes place, because the opposing pressure of the navicular bone is reduced on account of the imperfect play of the muscles and their unfavorable position. If, however, the pressure is relieved in utero, the length of the neck is evident at birth."

The superior articular surface of the talus is displaced posteriorly, so that the cartilage approaches nearly to the posterior inferior border. It appears longer and narrower than is normally the case. In our specimen, this articular surface is continuous with the inferior articular surface in the outer half. The lateral articular surfaces are very unequally developed. The external is filled with fibrous tissue in the posterior portion, while its anterior part is pushed nearer the neck. The internal is very small. In this particular our specimen is similar.

In the calcaneus the changes are simply an excessive representation of the fœtal over the adult bone. The articular surface for the talus inclines onward and backward, and its highest point does not reach the highest point of the bone. Anteriorly, it extends close to the cuboid articular surface; such a position of the articular surface forms supination. The body of the calcaneus and the neck are of equal length. The processus anterior is greatly developed in height and is out of all comparison with that of the new-born. The long axis is so bent upon itself that a concavity exists upon the inner side, and the tuber calcanei and processus anterior appear strongly bent to the same side. The articulation for the cuboid is entirely upon the mesial side of the neck. This bend in the axis of the bone and the position of the cuboid articular facet produce great displacement of the fore-foot at Chopart's joint.

The sustentaculum tali is placed at a much deeper level, and is very imperfectly developed. In extreme cases it is wanting, since the supination of the foot prevents its growth from pressure upon the malleolus internus. The similarity between our specimen and the new-born club-foot is striking, except for the degree and the nearthrosis. In the navicular bone, the lateral border is narrower than normal, while the inner border is thicker. This change is ascribed to the freedom from pressure for the inner border, and to the plantar flexion and supination for the external border.

The anterior and posterior articular surfaces nearly touch upon the inferior surface. The cuneiform articular surfaces are displaced toward the mesial border, while the talus articular surface reaches less closely to the inner border than is normally the case. These changes are evidences of pressure in the sense of adduction. The navicular bone is consequently triangular in shape, being narrower externally and toward the planta pedis.

The tuberosity is wanting or rudimentary. The changes in the cuboid are not so constant nor marked as in the calcaneus. As before stated, the relation of the inner to the outer border in percentages is fifty degrees for the new-born and fifty seven for the adult (Arby) cuboid. In club-foot, however, the anterior and posterior articular surfaces converge less externally, and the bone is more quadrilateral. It is principally, however, the anterior surface which inclines less obliquely outward and backward. The tuberosities cuboidii which bound the posterior border of the sulcus for the peroneus longus are not developed, so that the vertical diameter is much diminished. The thickening of the bone behind the sulcus is scarcely noticeable. The tuberosity is not developed, as its relations to the tendon have been lost by the displacement of the tendon upon the calcaneus. The similarity between these two bones (*i.e.*, navicular and cuboid), in the new-born and in our specimen, are marked. The cuneiform bones are arranged behind rather than alongside one another. Their posterior surfaces incline obliquely backward. The tibia and fibula are less altered. They are rotated inward (most marked) in their lower third. The malleolus externus instead of being posterior is anterior, and the transverse axis of the joint runs from behind and internally outward and externally.

It is also interesting to note the new articular facets found in club foot. In the club-foot of the new-born child new articular facets (nearthroses) are developed. 1. On the mesial side of the malleolus internal is found an articular facet which articulates with a similar facet upon the mesial and superior surface of the navicular bone. This articulation is entirely separate from the talo-navicular joint, and against its capsule rests the tibialis posticus tendon as it ascends beneath the naviculare. 2. Between the internal malleolus (its inferior surface) and neck of the talus. 3. Between the malleolus externus and the calcaneus.

In our specimen the nearthroses are more numerous, and are as follows: 1. Between the posterior border of the tibia and the calcaneus. 2. Between the internal malleolus and the navicular. 3. Between the internal malleolus and the cuneiform (internal). 4. Between the external malleolus and the calcaneus. 5. Between the sustentaculum tali and the inferior surface of the navicular bone. 6. Between the navicular bone and the talus at the junction of the body and the neck. 7. Between the postero-internal border of the cuboid and the calcaneus beneath and anterior to the sustentaculum tali.

The tendons in club-foot of the new born vary as follows:

The flexor longus hallucis runs in a groove on the talus and tibia into the soft parts beneath the plantar fascia, without touching the calcaneus.

The peroneus longus runs from the malleolus externus over and beneath the calcaneus. It does not touch the cuboid bone. The tibialis posticus runs from the posterior surface of the tibia over the border of the malleolus internus. These changes in the position of the tendons existed also in our case, though their displacement was more marked than has been described in the club-foot of the new-born or child.

These changes in the shape of the bones, the displacement of the tendons, the approximation of the points of origin and insertion of the muscles, and the new articular facets, are sufficient evidences of a force exerted upon the foot in the sense of plantar flexion at the ankle-joint, and supination and adduction in the talo tarsal joint. This pressure, which is produced in utero, can be seen in the great majority of new born children, but in so mild a degree that walking alone is sufficient to produce enough formative and dorsal flexion to correct it.

Chondrification is complete by the seventh or eighth week of fœtal life. The articulations begin to be formed at this time, and are completed at the fourth month. Short and slight pressures within the joint, owing to the softness of the cartilaginous skeleton, and the rapidity of growth in the foot, cause from this time on deformities in the bones, and secondarily in the position of the tendons.

Since the abnormal positions take place before the use of, and at the time of, the formation of the muscles, rectification does not take place afterward, because the bones have become altered in shape and the muscular attachments are approximated.

The earlier in fœtal life such malpositions are initiated, the more pronounced will be the subsequent deformity.

After birth the muscles tend to maintain or increase an existing deformity. In the adult congenital club-foot, however, there is added another factor in the production and intensification of the deformity, namely, in the weight of the body in walking. These changes, so

far as this dissection has shown, consist: 1, In an excessive increase of the deformities found in the bones of the new-born. 2, In additional nearthroses. 3. In an increased plantar flexion at the talo-crural joint. 4. In a marked supination and adduction in the calcaneus. 5. In an extensive displacement of the navicular and cuboid bone to the mesial side of the talus and calcaneus. 6. In a pronounced rotation of the tibia and fibula.

A normal foot at rest is one in which the position is one of moderate supination, slight adduction with plantar flexion. The axis in such a foot runs in a frontal direction from right to left in the talo-crural joint, and the motions of flexion and extension take place upon the axis. Flexion is always accompanied here with slight adduction. All muscles before this axis are dorsal flexors (extensors). Those behind it are plantar flexors (flexors).

The mid-position is one in which the foot is at right angles to the leg, *i.e.*, ninety degrees. Dorsal and plantar flexion can be carried to thirty-nine degrees in addition. Pronation and supination occur between the talus and the foot, *i.e.*, the talus, the calcaneus, cuboid, and navicular bones. The axis of motion is, if continued forward and backward, through the calcaneus from behind, outside and below, anteriorly above and within, passing through the sustentaculum tali and the neck of the talus. On account of the direction of this axis we must consider it as made up of three axes: a sagittal, about which pronation and supination occur; a perpendicular, about which ab- and adduction occur; and a frontal, about which flexion and extension occur. With supination, adduction and plantar flexion take place. With pronation, abduction and dorsal flexion. The muscles situated externally to this axis are pronators, abductors, and dorsal flexors. Those situated internally are supinators, adductors, and plantar flexors. For this reason, the tendo Achillis lying behind the axes in the talo-crural joint and to the inner side of the axis of motion in the talo calcanean becomes a plantar flexor at the talo-crural and a supinator at the talo-calcanean. Hence all tendons situated behind and to the inner side of these joints cause, when shortened, first plantar flexion at the talo-crural, and subsequently plantar flexion, supination, and adduction in the talo-calcanean and navicular joints.

It must be remembered, however, that even the mid-position in the adult is attended with a slight supination in the talo-calcanean joint, and that in the new-born this supination is often quite pronounced. For this reason a greater frequency exists in all deformities tending to varus over calcaneus or calcaneo-valgus. Such supination in foot axis corrected by the simple mechanism of walking is overlooked as being a deformity, and only that degree is so classed in which supination is not corrected by walking. Leuffenbach, Hueter, and Adams have shown that this difference in the axes of motion in the foot of the new-born and that of the adult allows of a greater supination without an increased plantar flexion and adduction in the former, while in the latter greater pronation is allowed. In the new-born the special characteristics of the talus are increased length of the neck and its downward and inward direction, with an articular surface upon its inner side, the angles of displacement being 15° and 45°, respectively. The long axis of the articular surface is midway between a vertical and horizontal plane and is oval in shape, whereas in the adult this surface is in a transverse plane and is ovoid. This difference is due to the fact that the axis of talus in the child is nearer the axes of motion between the talus and calcaneus than in the adult, and hence the motion at the talo-tarsal joint is more extensive and the joint surface more rounded. In the calcaneus, the great length and heighth of the processus calcanei, the oblique inclination of the superior articular process to the inner side, and the deep position of the sustentaculum tali, are the principal features. The inclination of the superior articular process downward and inward mainly, and to a less extent outward, favors supination. The reverse is the case in the adult, where pronation is favored. In the new-born the length of the neck is equal to that of the body. In the adult it is only one-third to one half the length of the body, owing to the pressure of the cuboid bone in the pronated position. The sustentaculum tali is deeply placed and slightly developed. The reverse condition is present in the adult.

Very slight differences exist in the cuboid except in the length of their outer borders. In the new-born this is represented in per cent. as 50° of the inner border. In the adult it is 57°.

In the treatment of a congenital club foot it is necessary to reduce the plantar flexion, the supination, the displacement at Chopart's joint, and the rotation of the leg inward. This replacement of the foot must be done so that the normal axes of motion are restored as completely as is possible. This can be accomplished either by the development of new articular facets with perfect motion, or by the extirpation of bone and syndesmotic or anchylosed joints with less perfect motion. The important period of life for the accomplishment of a complete restoration of the foot with perfect motion is, strictly speaking, the first thirty months of life. During this period the growth of the foot is relatively greater than any other part of the lower extremity.

Mechanical force and at the most tenotomies and fasciotomies are sufficient to correct deformities at this time. After this period great reliance upon the development of new articular facets becomes less and less, and we must trust more and more to operative procedures, viz., tenotomies, fasciotomies, talus extirpations, and cuneiform osteotomies. Which of these operations we select, and the particular method by which we accomplish them, is to be decided by the kind of deformity, the degree, and the special peculiarity of the case. For the more pronounced deformities of early youth, where mechanical treatment, fasciotomies, and tenotomies have been unsuccessful, or where no treatment has been used, the talus extirpation alone, or with a very limited wedge between the os calcis and cuboid bone, or within the os calcis, allows a flexion of the foot to 90° at the talo-crural, a relief of the supination in the os calcis, and a reduction in the displacement at Chopart's joint. In the adult the question becomes one of the extent of the equinus over the varus, or whether they are both equally marked. If the equinus is the marked deformity, provided tenotomy has not allowed of its reduction, talus extirpation. If varus is the marked deformity and the equinus is relieved by tenotomy, cuneiform osteotomy at Chopart's joint. If both are equally involved in the production, talus extirpation and cuneiform osteotomy. It should be the aim of the operator to relieve the deformity completely and at once. No apparatus, except possibly a high-soled shoe, is required when this is accomplished. No one would think of resorting to osteotomy or extirpation of the talus as a primary operation in the growing foot. It is enough here to divide the tendons and fascia wherever they oppose a replacement of the foot, and an appropriate after-treatment. In the foot, however, where growth is completed or nearly so, the conditions are not the same. Tenotomies and fasciotomies are done as a preliminary step in the operations of talus extirpation or cuneiform osteotomy, in order to determine how extensively they are to be carried out. No single method of operation, whether it be in the class of tenotomies, fasciotomy, or a bone operation, will suffice in the compound deformities of the third degree, and there should be no hesitancy in carrying out the idea of complete and immediate restoration of the foot in adults, especially, for the mortality, under antiseptic precautions, is less than one per cent. In fifty cases of inveterate club-foot in which a bone operation has been done, I have never seen a death, nor a case of infection except in one case. This case was operated upon a second time with a good result, the whole course of the treatment lasting five months.

THE VALUE OF ELECTRICITY IN DIAGNOSIS AND PROGNOSIS OF AFFECTIONS OF THE PERIPHERAL NERVES.[1]

By WILLIAM M. LESZYNSKY, M.D.,

NEW YORK.

LECTURER ON MENTAL AND NERVOUS DISEASES AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; NEUROLOGIST TO THE DEMILT DISPENSARY, ETC.

HAVING been asked to limit my remarks to the value of electricity in the diagnosis and prognosis of disease of isolated peripheral nerves (neuritis and nerve injuries), I shall only venture to present some of the most prominent features relating to this subject.

It would be superfluous before such a body to dwell in detail upon the essential methods of an electrical examination, or to refer to the various batteries. Whatever I may say will no doubt seem trite to the critical members of this Society, who are all more or less familiar with the use of electricity in diseases of the nervous system. To other physicians, not endowed with such special knowledge, a discussion of this nature is not only timely, but of the greatest practical importance.

During the last ten years I have devoted much time and attention to the study of electrical reactions, particularly in the various forms of disease affecting the peripheral nerves, which so often result in motor paresis or paralysis. My conclusions are therefore based upon personal observation in a large number of cases, and are in a great measure confirmatory of the claims of others.

It has been very aptly said: "The popular theory is that the carrying out an electrical investigation requires no special training, and is within the reach of anyone possessing a battery and a superficial knowledge of the medical applications of the current to the human body. . . . The ablest physician, the most consummate neurologist, if he has not submitted himself to the conditions required, and passed through the ordeal of discipleship, will fail to obtain reliable results. . . . But little additional light is shed upon the practical issues of the case by the reaction in a typical instance of infantile or lead paralysis, or of advanced progressive muscular atrophy. Where electro diagnosis is of paramount importance is at the beginning, during the insidious stage of numerous neuropathies."[2]

Comparatively little, or no attention at all, has been given by the general practitioner to the subject of electrodiagnosis, while the neurologist devotes too little time to its study. In all discussions or teachings on medical electricity too much stress has been laid upon its potency or uselessness as a therapeutic agent; while its importance in diagnosis and prognosis has been insufficiently recognized or neglected. The preliminary steps toward success in the study of the affections of the peripheral nerves, particularly where paresis or paralysis is a prominent symptom, consist in the acquirement of a practical familiarity with the position of the principal so-called "motor points," and a correct interpretation of the various electro diagnostic phenomena resulting from an examination of the nerve-trunks and muscles.

By this means we can satisfactorily determine, in the vast majority of cases, whether the disease is situated between the nucleus and the periphery of the motor nerves, or elsewhere. In two similar cases, whose pressure paralysis is of equal severity, the anatomical causes may vary considerably in their extent and intensity. It is only after an electrical examination that any conclusion can be drawn as to the approximate degree of damage to the nerve.

We are also enabled to state, almost accurately in many instances, what the probability is as to recovery, and to express an opinion as to the duration of the paralysis:

1. Preservation of faradic irritability in nerve and muscle, with only very slight decrease as compared with the healthy side, when found two weeks after attack, is of favorable import. Recovery usually takes place spontaneously within a few weeks (see Cases I. and II.).

2. The faradic irritability in both nerve and muscles may be very markedly diminished and accompanied by change in the character of the muscular contraction, which is slow and somewhat protracted. This may be associated with "qualitative" as well as "serial" changes found upon examination with galvanism, *i.e.*, the galvanic excitability in the nerve is present, though diminished, while in both nerve and muscle AnCC > CaCC (the contraction at the closure at the positive pole is greater than at the negative). This has been designated by Erb as the partial reaction of degeneration. It has been known to ultimately advance to complete R. D. Recovery usually takes place in a few months.

3. When the faradic irritability is lost in nerve and muscle, the prognosis remains doubtful. It is usually accompanied by loss of galvanic excitability in the nerve. When galvanism is applied to the muscle it contracts slowly, and the reaction may be more marked at the anodic opening than at the cathodic closure. There may also be increased irritability in the muscle as shown by a marked contraction being elicited by a current which has no effect whatever upon the healthy side.

This constitutes the reaction of degeneration (R. D.) and is of grave significance. The prognosis is doubtful or bad, due consideration being observed as to the cause of the lesion. These patients do occasionally get well, but more rarely when the facial nerve is affected than the nerves of the extremities. As a matter of fact the muscles involved may show various gradations in the character of their galvanic reaction. In my experience the persistent increase in the galvanic excitability influences the prognosis more unfavorably than a mere change in the polar reactions. This I have found to exist in cases of facial paralysis, but I have never seen a case of long standing—a year or more—where a reaction in the muscles to galvanism could not be demonstrated.

In the extremities, however, it is well known that when recovery does not take place, and the musculature atrophies, the galvanic irritability gradually diminishes, and ultimately no contraction can be obtained even with the strongest currents.

It has always seemed to me that there is a decided difference in the course of a facial paralysis as compared with that of nerves in the extremities. It is rare to see atrophy of the facial muscles after a persistent paralysis from the usual causes, while in the extremities atrophy is not at all uncommon. The return of faradic irritability in the facial muscles does not necessarily imply a recovery from the paralysis. I have found it present in cases that were from two to ten years' duration and of undoubted peripheral origin. See Case III., in which R. D. had been present and six months later faradic irritability returned, but motility was not restored.

The following case is still under observation: Annie D——, thirteen years of age. Left peripheral facial paralysis of ten years' duration. Right facial nerve reacts to faradism 30 mm.; left, 35 mm.; right facial muscles, 32 mm; left, 35 mm. (slow).

In the *Berliner klin. Wochenschr.*, October 16, 1893, Placzek reports four cases of peripheral paralysis (facial nerve, 3; brachial plexus, 1), that had existed for periods ranging from two years to twenty-five years (2, 9, 12, 25). Faradic irritability was preserved in both nerve and muscles. There was only slight quantitative decrease. Galvanic excitability was only slightly increased. The character of the muscular contractions was normal. Thus it is clearly shown that despite the paralysis having persisted unchanged for many years, and the nerve being impervious to the strongest voluntary impulses, its reaction upon electrical excitation indicates only a slight quantitative change in irritability. He asks "How are these phenomena to be reconciled with the current teaching as to the existence and course of peripheral paralysis?"

[1] Read at the meeting of the New York Neurological Society, February 6, 1894.

[2] De Watteville.

The only explanation given is based upon the assumption of Erb, that the conductivity in nerves depends on the axis cylinders, while that of electrical irritability exists in the medullary sheath. This view has been confirmed by the experiments of Schiff and Grünhagen [1] Placzek therefore concludes that in the cases reported the presence of an axial neuritis may be the cause of the apparently irreconcilable phenomena. I would hardly be willing to admit that these cases vitiate the teachings as to the usual course of the electro diagnostic phenomena. It seems to me that in old cases accompanied by the persistent classical reaction of degeneration, in which there is complete motor paralysis and muscular atrophy, the difference between the two classes is merely one of degree as to the pathological process.

A further study of the electrical reactions in old cases of peripheral paralysis may show that in the absence of atrophy the faradic irritability will be found present in every case.

On the other hand, motility may be restored in muscles of the extremities, yet faradic irritability may remain absent, or R D may be demonstrable.

It is well to bear in mind that the same electro-diagnostic phenomena occur whether the lesion be situated in the nucleus or in the course of the nerve trunks. When an eye muscle is paralyzed it is either the result of a lesion at the nucleus, in the trunk or branches of the nerve, or in the intramuscular nerve-elements themselves. The action of the current cannot be sufficiently circumscribed in order to produce isolated contraction of individual muscles. Even if such an examination were feasible, electricity could not aid us in making a diagnosis as to the location of the pathological process. As an element in prognosis it is valueless for the same reason.

The direct application of an electrode and the current to the ocular conjunctiva is a painful procedure and is rarely tolerated by the patient. Since the use of cocaine it was hoped that electricity could be applied to the individual ocular muscles after producing anæsthesia of the surface of the eyeball This hope has not been realized. It has been advised, and also attempted, to pierce the conjunctiva with a needle attached to one of the poles of the battery, and thus apply the current directly to the affected muscle. The writer has tested this as a method of treatment in a number of cases, but was forced to abandon it. Even in the hands of an expert it is not unattended with danger to the delicate structures of the eye. This is especially so regarding the use of the galvanic current. The facial nerve and the nerves of the upper extremities are the most accessible to electrical examination, as well as the most frequently affected by disease. The following histories selected from my case books will serve to illustrate the practical utility of electricity as an aid in diagnosis, and also as an auxiliary method in establishing an almost absolute prognosis:

Case I. *Peripheral Facial Paralysis (Traumatic).*—November 1, 1892. A. K——, a boy, ten years of age, was struck by a base-ball on right side of face, and all branches of the nerve became paralyzed within twenty four hours. He was seen three days after the injury, when paralysis was found to be complete. There was also slight disturbance of the sense of taste on the anterior two-thirds of the tongue on the same side. Slight diminution in faradic irritability in nerve and muscles. Left, 10 mm.; right, 15 mm. Two weeks later the motility was returning in facial muscles, the faradic irritability being only very slightly diminished —13 mm. Galvanic reaction normal. A favorable prognosis was given. Complete recovery three weeks later without treatment.

Case II. *Peripheral Facial Paralysis from Exposure to Cold.*—November 9, 1893. Miss G——, seventeen years of age. When seen three days after beginning of attack there was complete facial paralysis upon the right side. No involvement of palate, but loss of taste on the anterior two thirds of tongue on the same side. The left nerve and muscles reacted to faradism 10 mm.; right, 20 mm., showing an early decrease in faradic irritability.

November 16 —Faradism: Left, 10 mm.; right, 15 mm. Galvanic reaction normal; prognosis, good.

December 3 —Faradism: Left, 10 mm; right, 18 mm. Motility partly restored in facial muscles.

January 20, 1894 —No evidence of paralysis. Faradism: Left, 10 mm.; right, 20 mm. Complete recovery within ten weeks without treatment.

Case III. *Peripheral Facial Paralysis from Exposure to Cold.*—October 25, 1891. Miss K——, twenty-four years of age. After sailing in a storm became paralyzed on right side of face. All branches involved. Was first seen by me nine weeks after attack. Left nerve and muscles reacted to faradism 14 mm.; right, no reaction. Galvanism: Left, 2 Ma CaCC, normal in nerve and muscles; right, no reaction in nerve. Muscles react slowly to 1 Ma AnCC > CaCC. In other words, the reaction of degeneration is present. An unfavorable prognosis was given.

December 1.—The galvanic excitability in the muscles is always found increased.

January 31, 1892.—Although the faradic irritability has returned in nerve and muscles (quantitatively diminished) recovery is incomplete, and accompanied by secondary contracture in the zygomatics.

June 4.—Condition unimproved.

Case IV. *Peripheral Facial Paralysis from Exposure to Cold.*—February 13, 1893. Mr. M——, merchant, forty eight years of age. Two days after riding on the platform of an elevated railroad-car during a cold night he first noticed paralysis of the left side of face. All branches are affected. No interference with taste. Was seen three days after attack. Right nerve and muscles react to faradism 14½ mm.; left, 20 mm. (slow). Galvanism: Right, 1½ MaCC; left, 2 Ma AnCC = CaCC.

March 1st.—Left, loss of faradic reaction in nerve and muscles. Loss of galvanic irritability in nerve. Facial muscles react slowly to 1 Ma AnCC > CaCC, showing the reaction of degeneration. Prognosis doubtful.

February, 1894 (one year after onset of attack).—Recovery was almost complete except in lower facial muscles.

Case V. *Traumatic Neuritis of Left Ulnar Nerve.*—William H——, born in England, thirty years of age; diamond polisher. Was first seen February 26, 1889. Three weeks before he had been cut on the left wrist by a broken bottle. The wound had healed. He complained of numbness and tenderness on pressure over the ulnar distribution in the palm. Causalgia: Severe pain at night. Paralysis affecting the two ulnar fingers. There was anæsthesia in the hand in the course of the ulnar branches. Some atrophy of the adductor pollicis and the hypothenar group of muscles. Faradism: Right nerve and muscles, 14½ mm.; left, no reaction below the wrist. Galvanism: Ulnar nerve—right, 2¼ Ma CaCC; left, no reaction in forearm. Muscles—right, hypothenar group interossei and adductor pollices, 6 Ma CaCC; left, hypothenar group interossei, 6 Ma AnCC > CaCC, slow and feeble.

April 5th.—Excessive pain had continued and prevented sleep. Exploratory incision showed that the nerve had been cut across by the injury, and it was found in a condition of typical degeneration. The divided ends were sutured and the wound closed.

May 14th.—Pain had subsided. Anæsthetic area had diminished, and the tactile sensibility was improved. Faradism: Ulnar nerve at elbow 15 mm., only in adductor pollicis. No reaction in hypothenar group. Galvanism: 4 Ma AnCC, affecting adductor pollicis only.

October 24th.—The nerve conduction was steadily improving, so that 5 Ma CaCC produced a reaction in the hypothenar group. The strength in the hand rapidly increased and it was ultimately restored to usefulness.

[1] Zeitschr. f. Med., Bd. 29.

Case VI.—*Paralysis of Brachial Plexus (Bilateral).*—F. S——, aged twenty-five, born in the United States, porter. Was first seen by me September 6, 1890, and gave the following history: While intoxicated he fell asleep on the roof of his house, during a chilly night, August 23d (two weeks ago). Was carried to bed in the early morning and awoke in the afternoon with both arms paralyzed. There was numbness in the arms and fingers, which disappeared in a few days. No pain, no history of syphilis or rheumatism. Lower extremities not affected. While asleep on the roof he was wearing a stiff shirt collar, and he was told that his head was extended backward.

The following condition was found upon examination: Right upper extremity: Paralysis of deltoid, infraspinatus, teres minor, and biceps group. Paresis of supinators and extensors. No triceps jerk. No atrophy. No objective sensory disturbance, but some tenderness on pressure over supraclavicular portion of brachial plexus, causing radiation of pain through the entire arm. Median and ulnar distribution not involved. All nerves and muscles react well to faradism, 23 mm., and also upon irritation at Erb's supraclavicular point. Galvanic reactions normal.

Left upper extremity: Paralysis of deltoid, infraspinatus, and teres minor biceps group and latissimus dorsi. Paresis of the subscapularis and teres major, triceps, supinators, and extensors. No triceps jerk. No atrophy. No sensory disturbance. Tenderness on pressure over the brachial plexus in the neck. Median and ulnar nerves normal. The deltoid, triceps, and biceps group react well to faradism, 26 mm.; musculo spiral nerve, 31 mm.; extensors, 35 mm. (feeble). Galvanic reaction normal. Both shoulder joints relaxed and paretic muscles are flaccid. Lower extremities in good condition.

The treatment consisted in the application of blisters over the points of tenderness and the use of the galvanic current. A favorable prognosis was given. By the end of October recovery was complete.

From the foregoing history the distribution of the paralysis and the painful pressure points the diagnosis was made of traumatic neuritis of the brachial plexus resulting from pressure. The preservation of faradic irritability proved of service in forming a prognosis. This is representative of a class of cases of peripheral paralysis where the faradic irritability is preserved (or only slightly diminished) as well as all forms of sensation.

Case VII. *Spontaneous Degenerative Neuritis of the Brachial Plexus.*[1]—A man, thirty eight years of age, shortly after exposure to cold (without antecedent history of joint disease or injury) suffered from severe paroxysmal pain in the left shoulder, rapidly followed by paralysis of the deltoid. After short but varying intervals of freedom from acute pain another paroxysm would occur, accompanied by additional paralysis. These attacks, extending over a period of four weeks, involved all of the muscles innervated by the circumflex, suprascapular, subscapular, musculo-cutaneous, and musculo-spiral nerves. There was anæsthesia in the domain of the circumflex, external cutaneous, and radial nerves. Well-marked atrophy with the reaction of degeneration existed in all of the paralyzed muscles excepting the biceps group, in which only a "partial R. D." was demonstrable. The median and ulnar nerves were not involved. Almost complete recovery took place at the end of two years. The biceps group, presenting "partial R. D.," recovered first, while the supinator longus and the extensors of the forearm, exhibiting "complete R. D.," were the last to show signs of improvement.

If electricity is to be of any service to us in ascertaining whether the nerve-trunk has been divided or not as a result of traumatism, the examination must be made as soon after the injury as possible. We can then determine at once if special surgical interference is necessary. Should two or three weeks elapse before such examination it will be impossible to state whether the absence of reaction is due to traumatic neuritis or to complete division of the nerve. Exploratory incision would then be called for.

The tests with the galvanic current require adequate apparatus and a working knowledge of the relationship between electro-motive force, resistance, and current strength. It also requires much time, patience, and perseverance. Hence its unpopularity.

The musculo-spiral nerve, which seems to lose its irritability more readily than most of the other nerves of the body, presents some special peculiarities that are worthy of note. In apparently healthy people I have very often failed to demonstrate the faradic reaction of this nerve, and was unable to satisfactorily account for its absence. This occurred, as a rule, in muscular individuals, in whom the examination is occasionally difficult. With the small electrode over the nerve I could not elicit a response, even with strong currents, while the extensors reacted normally upon direct excitation. In the absence of evidence of disease I attributed this failure to the action of the current producing muscular contractions *in situ* sufficient to throw the electrode aside. With the electrode, however, in the same position—without having been removed—and the galvanic current substituted, the response would take place promptly. It may be that in some of the cases the faradic anode was used, thus accounting for the absence of the usual reaction (*vide infra*).

In the *Berliner Deutsch. med. Wochenschr.*, 1892, p. 747, Dr. Karl Gumpertz claimed that it was possible to make the anticipatory diagnosis of lead paralysis and paralysis due to other forms of neuritis even in cases where the typical extensor paralysis is absent, and where the electrical reaction of the muscles suspected of disease is shown by the direct examination to be practically normal. He called attention to the fact that in the musculo spiral nerve excitation with the faradic anode fails to elicit a response, while with the faradic cathode a distinct reaction is produced. Subsequently this claim was found to be fallacious by Dr. J. J. Putnam,[1] of Boston. He discovered that this peculiarity in reaction also existed in a certain proportion of apparently healthy people. I have been enabled to fully confirm the statements of Dr. Putnam, but, like him, am at a loss to give a satisfactory explanation of this phenomenon. While the cathode of the faradic break current can easily be recognized by its greater effect upon motor and sensory nerves, this relative difference in the strength of the poles and their action is insufficient to account for this peculiarity.

I have thus far examined twenty three cases with the following result: With the faradic anode over the nerve no contraction could be obtained in three cases with a strong and painful current, excepting in the supinator longus. In two there was no reaction whatever in the distribution of the nerve. In all of these five a comparatively weak current gave a well-marked reaction—when the faradic cathode was applied. As was to be expected the extensors reacted normally upon direct excitation, invariably requiring a greater length of coil at the anode. I am making more extended investigation along this line, and hope to report the result upon some future occasion.

The following conclusions will no doubt serve to controvert a number of popular fallacies relating to this subject:

1. That the value of electricity as an accessory method in diagnosis and prognosis of disease of the peripheral nerves is not as universally recognized as its importance demands.

2. That the result of this procedure often furnishes corroborative and conclusive evidence where only a provisional diagnosis has been made.

3. That the necessary technical skill in successfully pursuing such investigation and correctly interpreting

INTRA-NASAL GROWTHS AS FACTORS IN AURAL AND LARYNGEAL CATARRH.[1]

By SARGENT F. SNOW, M.D.,

AURIST AND LARYNGOLOGIST TO THE HOUSE OF THE GOOD SHEPHERD AND THE SYRACUSE FREE DISPENSARY; MEMBER OF THE CENTRAL NEW YORK MEDICAL ASSOCIATION, THE SYRACUSE ACADEMY OF MEDICINE, THE ONONDAGA COUNTY MEDICAL SOCIETY, ETC.

Mr. President and Members: The paper I shall present is one that I read before the Onondaga County Medical Society September 15, 1891. My object and apology for resurrecting it is twofold:

First, because it contains observations on the middle turbinated region of the nose, which was then, and is now, of great interest to me, and which I believe has received too little notice even by the specialist, compared to its fertility as a source of neuralgic and catarrhal affections.

Second, because I can report the result of treatment in the patients mentioned.

Of the three cases mentioned, I would say, two occurred in private and one in dispensary practice, illustrating, I think, the importance of intra-nasal disease as a factor in middle-ear, pharyngeal, and laryngeal catarrh.

Hoping that you will pardon me, I read the notes as in the original article.

Case I.—Mr. N——, a young man twenty-five years of age; native born; generally robust, and of good family history. About four months ago he noticed an impairment in the hearing of his left ear, and a continuous noise as of escaping steam. This went on steadily, and, when he came to me for treatment, I found the left drum membrane slightly shrunken, with some opacity, especially in posterior quadrant; right drum membrane somewhat inflamed around edges and over malleus; left hearing distance, $\frac{4}{100}$; right hearing distance, $\frac{100}{100}$, or normal.

Examination by tuning-fork showed that in the left ear the bone conduction was ten seconds better than the air conduction; right ear normal; left Eustachian tube also in a state of catarrhal inflammation, air being with difficulty forced through it.

With such proofs before us, we could not doubt that the trouble was one of catarrh of the middle ear. No history could be elicited of acute trouble following any of the exanthematous fevers, or of pain in ears at any time; but by posterior rhinoscopy I found the post-nasal space roomy, numerous varicose veins and inflamed patches scattered over surface of membrane, particularly in neighborhood of Eustachian tubes; the posterior ends of both middle and inferior turbinates covered with pale, hypertrophied tissue. Anterior rhinoscopy showed septum a little deflected to right with large spur in lower third touching and pressing against inferior turbinated, and another marked thickening in the upper third projecting in front of, and pressing against, the middle turbinated, which was also enlarged; left nostril pretty well filled with hypertrophied tissue, the whole bathed with more or less mucus.

Upon inquiry, I found that the nasal trouble had been with him for a long time, while the ear affection was of comparatively recent origin, and we cannot doubt that it came by gradual extension from, or in sympathy with, the catarrhal inflammation within the nose. Do not understand me to say, in all cases in which there are septal deflections, ridges, or spurs, we will find catarrh of the middle ear, or that all catarrhal conditions of the middle ear come from septal deformities; far from it. I think there are many such deformities that are perfectly innocent, but I do believe that whenever a deformity or overgrowth in any portion of the nose causes a contact between two surfaces that are not normally in contact, we will have a catarrhal inflammation arising from such a contact, which, acting in conjunction with the climatic influences we have in this section, is very liable to extend to either the ear or throat.

Professor St. John Roosa, John N. McKensie, and other authorities consider that fully seventy-five per cent. of all ear troubles are caused by intra nasal disease. McKensie further says, in vol. viii. of the "Reference Hand-book:" "It is impossible to exaggerate the part which diseases of the nose play in the production of inflammatory conditions of the middle ear." And my experience thus far, gentlemen, fully confirms this view. In fact, since my attention was particularly called to the middle turbinated bodies by an article in the *New York Medical Journal*, vol. li., p. 309, 1890, written by Dr. O. B. Douglas, of New York, I have made more careful examinations of this section of the nose, and, as yet, have found no case of post-nasal, middle ear, or laryngeal catarrh which was not accompanied by marked evidences, past or present, of pressure or contact of some of the surfaces in this region.

Many of these cases have shown a perfectly normal condition of nose in lower third, both inferior turbinated apparently healthy, and patients claiming that they had no trouble in breathing, each nostril being perfectly free; their complaint, as they say, "is further back or down," sometimes in the ear, sometimes in the larynx, and often their only symptom is of "something dropping into the throat."

A close examination of the upper portions of the nose will show, almost invariably, some point or points of contact between the middle turbinated and the septum or the outer wall of the nose, which, though slight in many instances, is, I believe, the cause of a great, and perhaps the whole, part of the trouble, particularly if the contact be persistent.

Case II.—Mr. F—— is a public speaker with the well-known clergyman's sore throat. He has been troubled since childhood with nostrils closing up frequently, and, at certain seasons of the year, having asthmatic attacks. Often wakes and finds that he has been sleeping with his mouth open; extreme hoarseness coming on with the slightest cold; occasional ringing in the ears, and of late an excessive amount of saliva. One year ago there was a complete loss of voice for nearly three weeks.

Upon examination, I found the whole pharynx intensely congested; posterior wall showing granulated areas; uvula œdematous; anterior and lateral pillars of fauces infiltrated. Post-nasal space showed same general appearance as the pharynx. An anterior view of the nostrils disclosed to us the cause of his troubles, the membrane of both inferior turbinated being puffy and thickened, middle turbinated bodies very much overgrown in bony and membranous formation.

There are, of course, many points of contact and some inflamed and thickened tissue that must be relieved before we can expect to do our patient permanent good, granting that the nasal abnormality is the cause of his pharyngitis. In this instance, we have a man who uses his voice excessively, and at times, when he is weary, I have no doubt his vocal production is faulty. That, of course, has its influence on his condition, and will have to be looked into and corrected.

In support of this plan of treatment, I will quote from Lenox Brown, of London, in his last edition of "Disease of the Throat," p. 117. He says: "I have seldom failed to find the cause of the vocal lesion in the nose or pharynx, and a cure effected by surgical treatment of those regions, supplemented by educational correction of a functional fault in production."

I will not weary you with the full notes of Case III.—Suffice to say that he is a German, age twenty-two, referred to me by Dr. S——; general health good; been in

[1] Read before the Onondaga County Medical Society September 15, 1891. Read again before the Syracuse Medical Association March 21, 1893, giving result of treatment in the cases reported.

Case VI.—*Paralysis of Brachial Plexus (Bilateral).*—F. S——, aged twenty-five, born in the United States, porter. Was first seen by me September 6, 1890, and gave the following history: While intoxicated he fell asleep on the roof of his house, during a chilly night, August 23d (two weeks ago). Was carried to bed in the early morning and awoke in the afternoon with both arms paralyzed. There was numbness in the arms and fingers, which disappeared in a few days. No pain, no history of syphilis or rheumatism. Lower extremities not affected. While asleep on the roof he was wearing a stiff shirt collar, and he was told that his head was extended backward.

The following condition was found upon examination: Right upper extremity: Paralysis of deltoid, infraspinatus, teres minor, and biceps group. Paresis of supinators and extensors. No triceps jerk. No atrophy. No objective sensory disturbance, but some tenderness on pressure over supraclavicular portion of brachial plexus, causing radiation of pain through the entire arm. Median and ulnar distribution not involved. All nerves and muscles react well to faradism, 23 mm., and also upon irritation at Erb's supraclavicular point. Galvanic reactions normal.

Left upper extremity: Paralysis of deltoid, infraspinatus, and teres minor biceps group and latissimus dorsi. Paresis of the subscapularis and teres major, triceps, supinators, and extensors. No triceps jerk. No atrophy. No sensory disturbance. Tenderness on pressure over the brachial plexus in the neck. Median and ulnar nerves normal. The deltoid, triceps, and biceps group react well to faradism, 26 mm.; musculo-spiral nerve, 31 mm.; extensors, 35 mm. (feeble). Galvanic reaction normal. Both shoulder joints relaxed and paretic muscles are flaccid. Lower extremities in good condition.

The treatment consisted in the application of blisters over the points of tenderness and the use of the galvanic current. A favorable prognosis was given. By the end of October recovery was complete.

From the foregoing history the distribution of the paralysis and the painful pressure points the diagnosis was made of traumatic neuritis of the brachial plexus resulting from pressure. The preservation of faradic irritability proved of service in forming a prognosis. This is representative of a class of cases of peripheral paralysis where the faradic irritability is preserved (or only slightly diminished) as well as all forms of sensation.

Case VII. *Spontaneous Degenerative Neuritis of the Brachial Plexus.*[1]—A man, thirty eight years of age, shortly after exposure to cold (without antecedent history of joint disease or injury) suffered from severe paroxysmal pain in the left shoulder, rapidly followed by paralysis of the deltoid. After short but varying intervals of freedom from acute pain another paroxysm would occur, accompanied by additional paralysis. These attacks, extending over a period of four weeks, involved all of the muscles innervated by the circumflex, suprascapular, subscapular, musculo-cutaneous, and musculo-spiral nerves. There was anæsthesia in the domain of the circumflex, external cutaneous, and radial nerves. Well-marked atrophy with the reaction of degeneration existed in all of the paralyzed muscles excepting the biceps group, in which only a "partial R. D." was demonstrable. The median and ulnar nerves were not involved. Almost complete recovery took place at the end of two years. The biceps group, presenting "partial R. D.," recovered first, while the supinator longus and the extensors of the forearm, exhibiting "complete R. D.," were the last to show signs of improvement.

If electricity is to be of any service to us in ascertaining whether the nerve-trunk has been divided or not as a result of traumatism, the examination must be made as soon after the injury as possible. We can then determine at once if special surgical interference is necessary. Should two or three weeks elapse before such examination it will be impossible to state whether the absence of reaction is due to traumatic neuritis or to complete division of the nerve. Exploratory incision would then be called for.

The tests with the galvanic current require adequate apparatus and a working knowledge of the relationship between electro-motive force, resistance, and current strength. It also requires much time, patience, and perseverance. Hence its unpopularity.

The musculo-spiral nerve, which seems to lose its irritability more readily than most of the other nerves of the body, presents some special peculiarities that are worthy of note. In apparently healthy people I have very often failed to demonstrate the faradic reaction of this nerve, and was unable to satisfactorily account for its absence. This occurred, as a rule, in muscular individuals, in whom the examination is occasionally difficult. With the small electrode over the nerve I could not elicit a response, even with strong currents, while the extensors reacted normally upon direct excitation. In the absence of evidence of disease I attributed this failure to the action of the current producing muscular contractions *in situ* sufficient to throw the electrode aside. With the electrode, however, in the same position—without having been removed—and the galvanic current substituted, the response would take place promptly. It may be that in some of the cases the faradic anode was used, thus accounting for the absence of the usual reaction (*vide infra*).

In the *Berliner Deutsch. med. Wochenschr.*, 1892, p. 747, Dr. Karl Gumpertz claimed that it was possible to make the anticipatory diagnosis of lead paralysis and paralysis due to other forms of neuritis even in cases where the typical extensor paralysis is absent, and where the electrical reaction of the muscles suspected of disease is shown by the direct examination to be practically normal. He called attention to the fact that in the musculo spiral nerve excitation with the faradic anode fails to elicit a response, while with the faradic cathode a distinct reaction is produced. Subsequently this claim was found to be fallacious by Dr. J. J. Putnam,[1] of Boston. He discovered that this peculiarity in reaction also existed in a certain proportion of apparently healthy people. I have been enabled to fully confirm the statements of Dr. Putnam, but, like him, am at a loss to give a satisfactory explanation of this phenomenon. While the cathode of the faradic break current can easily be recognized by its greater effect upon motor and sensory nerves, this relative difference in the strength of the poles and their action is insufficient to account for this peculiarity.

Case I.—Mr. N——, a young man twenty-five years of age; native born; generally robust, and of good family history. About four months ago he noticed an impairment in the hearing of his left ear, and a continuous noise as of escaping steam. This went on steadily, and, when he came to me for treatment, I found the left drum membrane slightly shrunken, with some opacity, especially in posterior quadrant; right drum membrane somewhat inflamed around edges and over malleus; left hearing distance, $\frac{4}{100}$; right hearing distance, $\frac{100}{100}$, or normal.

Examination by tuning-fork showed that in the left ear the bone conduction was ten seconds better than the air conduction; right ear normal; left Eustachian tube also in a state of catarrhal inflammation, air being with difficulty forced through it.

With such proofs before us, we could not doubt that the trouble was one of catarrh of the middle ear. No history could be elicited of acute trouble following any of the exanthematous fevers, or of pain in ears at any time; but by posterior rhinoscopy I found the post-nasal space roomy, numerous varicose veins and inflamed patches scattered over surface of membrane, particularly in neighborhood of Eustachian tubes; the posterior ends of both middle and inferior turbinates covered with pale, hypertrophied tissue. Anterior rhinoscopy showed septum a little deflected to right with large spur in lower third touching and pressing against inferior turbinated, and another marked thickening in the upper third projecting in front of, and pressing against, the middle turbinated, which was also enlarged; left nostril pretty well filled with hypertrophied tissue, the whole bathed with more or less mucus.

Upon inquiry, I found that the nasal trouble had been with him for a long time, while the ear affection was of comparatively recent origin, and we cannot doubt that it came by gradual extension from, or in sympathy with, the catarrhal inflammation within the nose. Do not understand me to say, in all cases in which there are septal deflections, ridges, or spurs, we will find catarrh of the middle ear, or that all catarrhal conditions of the middle ear come from septal deformities; far from it. I think there are many such deformities that are perfectly innocent, but I do believe that whenever a deformity or overgrowth in any portion of the nose causes a contact between two surfaces that are not normally in contact, we will have a catarrhal inflammation arising from such a contact, which, acting in conjunction with the climatic influences we have in this section, is very liable to extend to either the ear or throat.

Professor St. John Roosa, John N. McKensie, and other authorities consider that fully seventy-five per cent. of all ear troubles are caused by intra nasal disease. McKensie further says, in vol. viii. of the "Reference Hand-book:" "It is impossible to exaggerate the part which diseases of the nose play in the production of inflammatory conditions of the middle ear." And my experience thus far, gentlemen, fully confirms this view. In fact, since my attention was particularly called to the middle turbinated bodies by an article in the *New York Medical Journal*, vol. li., p. 309, 1890, written by Dr. O. B. Douglas, of New York, I have made more careful examinations of this section of the nose, and, as yet, have found no case of post-nasal, middle ear, or laryngeal catarrh which was not accompanied by marked evidences, past or present, of pressure or contact of some of the surfaces in this region.

Many of these cases have shown a perfectly normal condition of nose in lower third, both inferior turbinated apparently healthy, and patients claiming that they had no trouble in breathing, each nostril being perfectly free; their complaint, as they say, "is further back or down," sometimes in the ear, sometimes in the larynx, and often their only symptom is of "something dropping into the throat."

A close examination of the upper portions of the nose will show, almost invariably, some point or points of contact between the middle turbinated and the septum or the outer wall of the nose, which, though slight in many instances, is, I believe, the cause of a great, and perhaps the whole, part of the trouble, particularly if the contact be persistent.

Case II.—Mr. F—— is a public speaker with the well-known clergyman's sore throat. He has been troubled since childhood with nostrils closing up frequently, and, at certain seasons of the year, having asthmatic attacks. Often wakes and finds that he has been sleeping with his mouth open; extreme hoarseness coming on with the slightest cold; occasional ringing in the ears, and of late an excessive amount of saliva. One year ago there was a complete loss of voice for nearly three weeks.

Upon examination, I found the whole pharynx intensely congested; posterior wall showing granulated areas; uvula œdematous; anterior and lateral pillars of fauces infiltrated. Post-nasal space showed same general appearance as the pharynx. An anterior view of the nostrils disclosed to us the cause of his troubles, the membrane of both inferior turbinated being puffy and thickened, middle turbinated bodies very much overgrown in bony and membranous formation.

There are, of course, many points of contact and some inflamed and thickened tissue that must be relieved before we can expect to do our patient permanent good, granting that the nasal abnormality is the cause of his pharyngitis. In this instance, we have a man who uses his voice excessively, and at times, when he is weary, I have no doubt his vocal production is faulty. That, of course, has its influence on his condition, and will have to be looked into and corrected.

In support of this plan of treatment, I will quote from Lenox Brown, of London, in his last edition of "Disease of the Throat," p. 117. He says: "I have seldom failed to find the cause of the vocal lesion in the nose or pharynx, and a cure effected by surgical treatment of those regions, supplemented by educational correction of a functional fault in production."

I will not weary you with the full notes of Case III.—Suffice to say that he is a German, age twenty-two, referred to me by Dr. S——; general health good; been in

[1] Read before the Onondaga County Medical Society September 15, 1891. Read again before the Syracuse Medical Association March 21, 1893, giving result of treatment in the cases reported.

this country one year, and for past three months has had difficulty with his throat; voice husky and easily fatigued, it having been, at one time, entirely lost. He first noticed a fulness in his head and nose ten months ago.

Examination showed a decidedly inflamed larynx, pharynx infiltrated with a very red track extending up along lateral walls to post nasal space; turbinated bodies puffy and in stage of commencing hypertrophy; bony union between left inferior turbinated and lower third of septum; many points of contact in both nostrils.

Topical applications to the vocal bands and pharynx have reduced the inflamed conditions existing there. Cleansing and applications to the nasal tissues, have given him, for the present, a good breathing space, though the bridge of bone and some points of contact still remain.

Are we warranted in considering these contacts and deformities as etiological factors of his laryngeal trouble?

Referring to Sajous's recent work on "Diseases of the Nose and Throat," p. 336, we find that he says: "Chronic inflammation of the vocal bands may result from repeated attacks of subacute laryngitis in connection with acute pharyngitis, but in the majority of cases it assumes the chronic form from the first, unpreceded by acute symptoms. Hypertrophic rhinitis is a frequent complication of this affection, the chronic catarrhal inflammation extending by continuity of tissue to the larynx, which is itself made subject to all the exacerbations which the nasal disease undergoes. A more frequent connection between the two diseases, however, is the irritation kept up by the post nasal discharges, which either drop into the larynx, or trickle down along the posterior pharyngeal wall until the interarytenoid commissure is reached; here they accumulate to a degree, and maintain the posterior portion of the larynx in a constant state of irritation, which is further aggravated by the coughing and hacking induced. This cause of chronic laryngitis is insisted upon by Bosworth, and I can well confirm his opinion."

Regarding prognosis Professor Douglass, in his very able article before referred to, says: "Chronic nasal catarrh, so called, is not so difficult of cure as has been supposed, for it is the result of removable causes in most cases."

In the face of these authorities, and the light of our present knowledge, what shall we do with cases of chronic nasal, aural, and laryngeal inflammation? Shall we patch them up with a gargle or spray, and send them adrift to soon become the prey of some quack who has push, enterprise, and the newspaper to help him; or, shall we see that they continue on to a removal of the cause, relieving the point of contact or pressure by such operative procedure as may be necessary, and carrying out the other treatment as may be indicated?

If we follow our plain duty, I believe that our results will be very satisfactory, and we can confidently expect to soon throw off the weight of opprobrium that has been hanging upon us as a profession because of our failure in the past to cure "catarrh."

Since reading the above before the County Society, gentlemen, I have continued treatment in the cases mentioned. Perhaps a description of their present condition will be of interest to you.

Case I.—The young man with middle-ear catarrh has proved especially interesting to me, strengthening my belief that pressure or contacts in the middle turbinated regions, have a marked influence over middle-ear troubles. During the first of his course of treatment I removed by the saw the shelf of bone spoken of, and by the galvano-cautery enough of the hypertrophied tissue to give him sufficient breathing space, meanwhile treating the ear carefully by inflation, vaporizing through Eustachian catheter, etc.

At the end of three months we found that no improvement had been made in his hearing distance, though his nasal catarrh was considerably relieved. I urged him to submit to a removal of a bean-like enlargement found on each middle turbinated, pressing against the anterior wall of the nose. This he refused, and I lost sight of him until December 14, 1892, when he returned, and examination showed right hearing distance $\frac{1}{100}$, left hearing distance $\frac{1}{100}$, a loss of three inches since first examination.

During the six months following I operated on the growths mentioned, with the result that his hearing distance in affected ear was increased to $\frac{10}{100}$, a gain of nine inches. Unfortunately he was called out of town, and we were again interrupted, though I am informed that he continues to improve. The same aural medication was given in this as in his first course of treatment.

If I had not already trespassed too much on your time, I would read you notes of several more cases, in which equally as good and better results have been attained after similar operation in the olfactory region, but in which my most careful ear treatment had failed to increase their hearing distance previous to relieving the contacts and pressures in the upper regions of the nose.

Added experience and the recent observations of good authorities, notably the article on "Cyst of the Middle Turbinated Bone," written by Professor Charles H. Knight, have substantiated the opinion I expressed in 1891, that pressures or contacts in the middle turbinated region were very important, and I would urge all who are doing intra-nasal work to examine this section thoroughly, not alone because of its relation to ear and throat troubles, but because of its close connection with asthma, hemicrania, and neuralgic affections of the head.

Operations here are not necessarily painful, if two or three applications of a twenty per cent. solution of cocaine be carried well in and along the lateral surfaces of the offending overgrowth; neither are they attended with much danger if proper after-treatment be given, though close discrimination should be used about the extent and manner of operating, removing only such portions as is necessary to relieve the pressure or contact.

Case II.—The clergyman has had a full course of operative treatment, and a most satisfactory result. During the past year he has had no attack of asthma, no pharyngitis, laryngitis, or ringing in the ears; neither has he been bothered by repeated colds, nor a stuffed-up nose. In a conversation last week he told me that he could not estimate in money the benefit he had derived. The specimens I now show you I removed from his nose by the cold snare. As you will see, they are partly cystic in character, and of unusual size (see photograph).

Case III.—The young German continued his treatment until the symptoms complained of were relieved, the voice being fully restored. The shelf across left nostril was removed by the electro-trephine, consequently the pieces taken out were not saved, though I recollect that it was a common osseous growth about an inch long.

In conclusion, let me say that I have no doubt the notes of other specialists will show fully as good results as those I have mentioned, and I would respectfully ask the general practitioner to not pass over the articles in his journals relating to rhinology, otology, or laryngology, but stop and carefully read a few of them. If he does so, I think disparaging remarks made about the treatment of chronic catarrhal affections will be less frequent.

117 East Jefferson Street.

The Duke of Westminster, although he is a vice-president of St. George's Hospital, refuses, so it is reported, to let any of his houses in the West End of London to medical men, fearing that their presence will frighten away his fashionable tenants.

AN EARLY OVARIOTOMIST.

The younger, and most of the older, members of the profession in America have little conception of the violent opposition there was, fifty and even thirty years ago, to the performance of operations on the abdominal cavity. Those who undertook such operations in the face of almost universal condemnation did so with their reputations in their hands. They believed they were right and they had the courage of their convictions, but their courage was of no mean order, and entitles them to grateful recognition by posterity. We have all heard of McDowell and Rogers and the Atlees, but we doubt if the name of Dunlap is as familiar to our readers as it deserves to be.

At the recent meeting of the American Gynecological Association in Washington, Dr. J. C. Reeve read a most interesting memoir (New York *Journal of Gynæcology and Obstetrics*, June, 1894) of this pioneer ovariotomist, Dr. Alexander Dunlap, of Springfield, O., whose death, at the ripe old age of seventy-nine, occurred in January last. Dr. Dunlap was born in Ohio, received his education, both academic and medical, in that State, married there, practised there, and died there. He was not a cultured man in the ordinary acceptation of that term, nor were books his companions. He studied, as most men of his time were obliged to study, in the school of experience. He knew little of what his predecessors had done or his contemporaries were doing, but struck out new paths for himself, undeterred by the reprobation of others less original and less courageous, and, in his ignorance of what other great minds had conceived and executed, unencouraged by their success.

Dr. Dunlap's first ovariotomy was performed in 1843, and up to 1868 his cases numbered thirty-eight. Of these nine had resulted fatally, one from an overdose of morphine administered by mistake. During his entire career he performed four hundred and twenty-eight abdominal sections, with eighty-three per cent. of recoveries.

His method of operating was primitive in the extreme. Dr. Reeve assisted him in some of his earlier cases, and the following are his words in describing them:

"Scalpel, forceps, and director were the only instruments provided. The abdomen was opened, the cyst exposed, then incised with the scalpel, and its contents caught in a wash-basin. Adhesions were separated as the cyst was withdrawn, or the incision was extended without hesitation in order to gain access to them. Bleeding from separated adhesions was checked by the application of cold water. In one case this was continued for twenty minutes and no evil results followed. In closing the wound the stitches were not passed through the peritoneum. The pedicle was transfixed with a ligature of heavy silk, each half tied separately, then one end carried around the whole and tied again; one end was then cut short and the other brought out at the lower angle of the wound, there to hang until separated by process of ulceration. This always required weeks, sometimes many months. In the case of a girl, aged thirteen, operated on by the writer, where this plan was followed, more than a year elapsed before the ligature came away, and this in spite of all measures to hasten it. This mode of treatment of the pedicle seems very strange in view of the fact that in Dr. Dunlap's first case both ends of the ligature were cut short, the pedicle dropped back, and the wound closed. There is not the slightest probability that Dr. Dunlap knew, even as late as 1868, that this was the plan pursued by Nathan Smith, in 1821, the second operator in the United States, and by D. L. Rogers, of New York, the fourth, in 1829. It looks very much as if, after his first case, he informed himself as to the plan followed by McDowell and Atlee, and made this step backward under the influence of their example."

"The treatment received by Dr. Dunlap," says the author of this most interesting biographical sketch, "was of the same kind as that meted out to McDowell. The comments of the *Medico-Chirurgical Review* of London, then the leading journal of the world, upon his operation are well known: 'We entirely disbelieve that it has ever been performed with success—nor do we think it ever will!' The extent, the bitterness, the persistency of the opposition to ovariotomy, the denunciation of those who performed it, can scarcely be imagined now. It is recorded in the pages of Peaslee and of Atlee. Nor was this feeling confined to this country. Mr. Ernest Hart has recently told us that in London, during the first attempts at ovariotomy, Dr. Robert Lee, then the leading obstetrician, openly stated that he was watching for a fatal case that he might cause the operator to be legally prosecuted! He who now, after fifty years of service, would indicate the most striking contrast between the profession as it is to-day and as it was when he entered it, would not find that contrast in the possession of anæsthetics nor in the triumphs of abdominal surgery, where even ovariotomy has sunk to a position of minor importance; but he would find it in the different spirit with which new doctrines, new measures, and new operations are received. The *Zeitgeist* of medicine has taken on an entirely different form from that of a generation ago."

THE DEVELOPMENT OF THE RAILWAY SURGEON.

The growth of the railway surgeon and of railway surgical service is, we believe, a feature of professional development peculiar to this country.

There are at present 147,704 miles of railways in the United States and Canada, and all but 17,088 miles are watched over, more or less, by surgeons in the employ of the corporations. The total number of railway surgeons is 5,466. The railways which possess a hospital system cover 36,751 miles; railways with a relief service, 13,446 miles; and railways with a surgical service and chief surgeon, 44,281 miles. There is a National Association of Railway Surgeons with a membership of 1,767 and an organ called *The Railway Surgeon*.

According to this journal there are over 120 chief surgeons, representing 82,032 miles of railway employing 3,384 surgeons, "all of which [*sic*] are working harmoniously under a chief surgeon, who in each instance has, to a greater or less extent, charge of the surgical department of the company he represents. We have great reason to rejoice and be glad and to congratulate this association on the work it has accomplished."

The Railway Surgeon admits that there are some who assert that there is no special field for railway surgery, which really cannot differ, so far as we can see, from any other surgery. We have also heard the complaint that

this country one year, and for past three months has had difficulty with his throat; voice husky and easily fatigued, it having been, at one time, entirely lost. He first noticed a fulness in his head and nose ten months ago.

Examination showed a decidedly inflamed larynx, pharynx infiltrated with a very red track extending up along lateral walls to post nasal space; turbinated bodies puffy and in stage of commencing hypertrophy; bony union between left inferior turbinated and lower third of septum; many points of contact in both nostrils.

Topical applications to the vocal bands and pharynx have reduced the inflamed conditions existing there. Cleansing and applications to the nasal tissues, have given him, for the present, a good breathing space, though the bridge of bone and some points of contact still remain.

Are we warranted in considering these contacts and deformities as etiological factors of his laryngeal trouble?

Referring to Sajous's recent work on "Diseases of the Nose and Throat," p. 336, we find that he says: "Chronic inflammation of the vocal bands may result from repeated attacks of subacute laryngitis in connection with acute pharyngitis, but in the majority of cases it assumes the chronic form from the first, unpreceded by acute symptoms. Hypertrophic rhinitis is a frequent complication of this affection, the chronic catarrhal inflammation extending by continuity of tissue to the larynx, which is itself made subject to all the exacerbations which the nasal disease undergoes. A more frequent connection between the two diseases, however, is the irritation kept up by the post nasal discharges, which either drop into the larynx, or trickle down along the posterior pharyngeal wall until the interarytenoid commissure is reached; here they accumulate to a degree, and maintain the posterior portion of the larynx in a constant state of irritation, which is further aggravated by the coughing and hacking induced. This cause of chronic laryngitis is insisted upon by Bosworth, and I can well confirm his opinion."

Regarding prognosis Professor Douglass, in his very able article before referred to, says: "Chronic nasal catarrh, so called, is not so difficult of cure as has been supposed, for it is the result of removable causes in most cases."

In the face of these authorities, and the light of our present knowledge, what shall we do with cases of chronic nasal, aural, and laryngeal inflammation? Shall we patch them up with a gargle or spray, and send them adrift to soon become the prey of some quack who has push, enterprise, and the newspaper to help him; or, shall we see that they continue on to a removal of the cause, relieving the point of contact or pressure by such operative procedure as may be necessary, and carrying out the other treatment as may be indicated?

If we follow our plain duty, I believe that our results will be very satisfactory, and we can confidently expect to soon throw off the weight of opprobrium that has been hanging upon us as a profession because of our failure in the past to cure "catarrh."

THE DEVELOPMENT OF THE RAILWAY SURGEON.

The growth of the railway surgeon and of railway surgical service is, we believe, a feature of professional development peculiar to this country.

There are at present 147,704 miles of railways in the United States and Canada, and all but 17,088 miles are watched over, more or less, by surgeons in the employ of the corporations. The total number of railway surgeons is 5,466. The railways which possess a hospital system cover 36,751 miles ; railways with a relief service, 13,446 miles ; and railways with a surgical service and chief surgeon, 44,281 miles. There is a National Association of Railway Surgeons with a membership of 1,767 and an organ called *The Railway Surgeon*.

According to this journal there are over 120 chief surgeons, representing 82,032 miles of railway employing 3,384 surgeons, "all of which [*sic*] are working harmoniously under a chief surgeon, who in each instance has, to a greater or less extent, charge of the surgical department of the company he represents. We have great reason to rejoice and be glad and to congratulate this association on the work it has accomplished."

The Railway Surgeon admits that there are some who assert that there is no special field for railway surgery, which really cannot differ, so far as we can see, from any other surgery. We have also heard the complaint that

railway surgeons were notoriously incompetent in neurological diagnosis, and that there was more need of railway neurology and medicine than of surgery.

We have no doubt, however, that the organization of railway surgeons into a national body will promote the material interests of the surgeons and render the work done by them more effective.

News of the Week.

Fear of Premature Burial.—The will of the late Mr. Edmund Yates contained a clause in which he expressed the desire that his jugular vein should be opened immediately after the physician had pronounced him dead, in order to prevent any possibility of his being buried alive. The medical man who performed the operation was to receive a fee of twenty guineas.

The Inheritance of Insanity.—Dr. G. Fielding Blandford, President of the Psychological Section of the British Medical Association, took as the subject of his opening address, "The Prevention of Insanity." One of the most important factors in the etiology of the disease, he said, is heredity. Sir Benjamin Ward Richardson has made the assertion that insanity is transmitted through the male line, but the speaker held that the reverse is the case, the taint passing through the female line rather than the male. He did not, however, insist so strongly on this point, holding that the safest rule was that no one, man or woman, who had had an attack of insanity, should marry.

Gift of Dr. Wilson Fox's Plates of Diseases of the Lungs to Medical Schools.—In a letter to *The Medical Press and Circular*, Drs. Sidney Coupland and W. R. Gowers direct the attention of the managers of medical schools in England, the Colonies, and America to the fact that there is a considerable number of the surplus sets of the colored plates of Dr. Wilson Fox's "Atlas of Diseases of the Lungs." These contain the most perfect representation of morbid states of the lungs ever produced. They will be of great value to medical schools, if framed and placed in the museum or post-mortem room. It is, therefore, proposed to give a set to each medical school the dean or manager of which desires it; a certain number will be reserved until October to give colonial medical schools an opportunity of obtaining them. Each set contains twenty-five colored plates. Brief descriptions can easily be prepared from the text of Dr. Fox's atlas and affixed to the plates. The cost of packing and transmission amounts to 1s. in the United Kingdom, 2s. 6d. for America and the Colonies. This sum should be sent, with the application, to Messrs. Mintern Bros., 84 Southampton Row, London, W. C.

The Cholera continues in somewhat milder form in St. Petersburg, the number of new cases averaging from twenty to twenty five per day, the mortality being, as usual, about fifty per cent. of those attacked. Isolated cases are reported from many towns throughout Holland, showing a widespread infection in that country. All steerage passengers for America sailing from Amsterdam or Rotterdam are subjected to a five days' quarantine before being allowed to embark. Amsterdam and Maastricht are the two cities where the disease prevails most extensively. One death from cholera has occurred near Cologne and several in the Danzic and Johannisburg districts in Prussia. The disease has passed down the river Pruth and invaded the surrounding districts in Bukowina, the capital of that province, Czernowitz, being seriously infected. The usual summer scare over a case of cholera nostras, "which is pronounced by the doctors to be a case of genuine Asiatic cholera," is reported from a town in Minnesota.

Lowered Duties on Drugs.—The Senate tariff bill lowers the duty on a number of drugs, that on castor-oil being reduced fifty six per cent. below the rate under the McKinley law, and that on epsom salts thirty-four per cent. Other reductions are, thirty per cent. on cod-liver oil, fifty per cent. on bicarbonate of soda, twenty per cent. on sublimed sulphur, eighteen per cent. on refined camphor, and twenty-five per cent. on strychnine. The duty on spectacle lenses is reduced from sixty to thirty-five per cent. ad valorem, a decrease of nearly forty-two per cent.

Fourpence a Visit.—An English physician advertises office consultations and medicine for fourpence, visits at the patient's house, including medicine, one shilling, attendance and medicine at the patient's home, 2s. 6d. Sixty cents a week is not an excessive charge for medical attendance, but it is probably all it is worth in the given instance.

The Plague Bacillus.—Several investigators in China, who have been studying the plague, have announced the discovery of a bacillus, the micro organism in each case being different from all the others. Although time alone will decide which of these claims, if any, is well founded, the presumption is that Kitasato's bacillus is the true one. The disease still prevails in Canton, but has nearly died out in Hong Kong. An official report places the number of deaths from the plague in the latter city up to the first of August at 2,504.

Women Medical Students in Glasgow.—At the graduation exercises of the University of Glasgow, held on July 26th, the degrees of Bachelor of Medicine and Master in Surgery were conferred on Marian Gilchrist and Alice Cumming. Professor Charteris delivered the address to the graduates, and in congratulating the female recipients of degrees he expressed a hope that the time would come when degrees would be bestowed which would do less violence to the sex, and that they would run as "spinster in medicine" and "mistress in surgery." The abbreviation of M.S., however, would not distinguish the sex. This is the first time in the history of any of the Scottish universities that a medical degree has been granted to a woman.

Intemperate Antivivisectionists.—On the occasion of the meeting of the British Medical Association in Bristol, the local temperance advocates of the place, taking advantage of the special opportunity of hearing the opinions of the medical profession on the temperance question, invited some of the leading medical visitors to a meeting held at the Hall of the Young Men's Christian Association. Mr. Joseph Storrs Fry, who had arranged to preside, happened to be also the president of the local Antivivisection Association. Several gentle members of the British Women's Temperance Society, who are also members of the Antivivisection Association, on learning

Essentials of Practice of Pharmacy. Arranged in the Form of Questions and Answers. Prepared especially for Pharmaceutical Students (Second Edition, Revised). By Lucius E. Sayre, Ph.G., Professor of Pharmacy and Materia Medica, of the School of Pharmacy of the University of Kansas. Philadelphia: W. B. Saunders. 1894.

This is one of the latest volumes of Saunders's Question Compends, intended, as its title explains, for the use of students in pharmacy. It appears to be admirably arranged, and ought to be of great assistance to the conscientious student who is making a final review before examination.

De la Maladie de Basedow, et en Particulier de sa Pathogénie. Par Frederick Chamberlain, Docteur en Médecine de la Yale Medical School, États-Unis, Docteur en Médecine de la Faculté de Paris. Paris: Henry Jouve. 1894.

In this excellent monograph Dr. Chamberlain treats quite exhaustively of exophthalmic goître, and especially of the numerous theories held at different times and by different observers of the pathogenesis of the affection. There is a list of forty-two cases in which operative treatment was undertaken, and the work concludes with a very complete bibliography, from the article of Graves in 1835, to one by Marie published the last day of February, 1894.

Traitement des Rétrécissements par l'Électrolyse Linéaire. Par le Dr. J. A. Fort, Ancien Interne des Hôpitaux, Professeur Libre d'Anatomie à l'École Pratique de la Faculté de Médecine de Paris. Paris: G. Masson. 1894.

In this exhaustive treatise of five hundred and fifty pages Dr. Fort sums up all there is to say in favor of linear electrolysis as a cure for stricture. In an introductory chapter the author speaks of linear electrolysis in general, and in the fourth chapter describes the mode of performing it, the intervening chapters being devoted to a recital of one hundred and forty cases of urethral stricture treated by this method. The next chapter contains the histories of twenty-seven cases of complicated and irregular strictures, and the good results obtained by the author. The sixth chapter is devoted to a consideration of the dangers of internal urethrotomy, and in the final chapter are the résumés of several works bearing testimony to the utility of the author's procedure. In the second part Dr. Fort treats of linear electrolysis applied to the relief of strictures of the œsophagus, and reports a number of cases (upward of thirty) in which this method was successfully employed. This procedure has one great advantage over electrolysis as usually practised in this country, in that it is completed at a single sitting.

The Essentials of Chemical Physiology for the Use of Students. By W. D. Halliburton, M.D., F.R.S. Pp. 166. London: Longmans, Green & Co., 1893.

This book is written in order to supply the student with directions for examining practically the most important of the subjects included under the head of physiological chemistry. It is also intended to serve as an elementary text-book. It is well illustrated, and is more complete than most of so called "Essentials" published for the benefit of the student.

Outlines of Insanity, an Attempt to present in a Concise Form the Salient Features of Mental Disorder; Tabulated and Arranged for Facility of Reference when drawing up Lunacy Certificates. Designed for the Use of Medical Practitioners, Justices of the Peace, and Asylum Managers. By Francis Walmsley, M.D. Pp. 154. London: The Scientific Press (Limited). 1892.

The purpose of this work is indicated fully in its title. It is a short popular exposition of insanity. The author has fulfilled his task creditably, and the book is printed in excellent style.

Congenital Affections of the Heart. By George Carpenter, M.D., Member of the Royal College of Physicians, etc. London: John Bale & Sons.

The book under consideration is the embodiment in printed form of demonstrations on congenital malformations of the heart, found of service to a class of students who failed to find in ordinary text-books explanations sufficiently precise and clear. The history of twenty-two cases is given, all the theories as to cause are considered, and a very careful survey of normal embryonic cardiac development is an interesting feature. As a supplement to larger works, as those of Rokitansky, Kussmaul, Peacock, and others, this fills a distinct want.

Clinical Manual for the Study of Diseases of the Throat. By James Walker Downie, M.B., Fellow and Examiner in Aural Surgery for the Fellowship, of the Faculty of Physicians and Surgeons, etc. New York: Macmillan & Co. 1894.

For the use of students and practitioners, this manual is dictated in great part by personal experience, and divided into two sections. In the first systematic examination of the throat is discussed, together with the various manifestations of disease. In the second and larger section individual diseases are considered in detail, according to their importance and frequency of occurrence, and medicinal and surgical treatment. For a book of small size, immense ground is covered and the suggestions given are of practical value and utility.

Practical Lectures in Dermatology. By Condict W. Cutler, M.S., M.D., Professor of Dermatology, University of Vermont, etc. New York and London: G. P. Putnam's Sons. 1894.

The excuse for this work, not the reason of its existence, the author states in the preface to be the request of the students in the medical department of the University of Vermont to have the lectures delivered in 1892 and 1893 published for convenient and ready reference. Prepared from stenographic notes, the fifteen lectures are here given with substantial accuracy, and consider only those diseases of the skin which every practitioner is called upon to diagnosticate and treat in an intelligent manner. The work is plain and practical, and commends itself to any busy practitioner. And herein lies its "reason for being," which needs no excuse.

Die Behandlung der Leukaemie. Kritische Studie Von Dr. H. Vehsemeyer. Berlin: S. Karger. 1894.

In this brochure the author presents a very exhaustive review of the various measures which have been tried with more or less success in the treatment of leucocythæmia. Dr. Vehsemeyer himself has had such good results in one case treated with the fluid extract of barberry, that he thinks this drug, or its alkaloid, berberine, should be given a further trial.

A Modern Wizard. By Rodrigues Ottolengui. G. P. Putnam's Sons, New York and London. 1894.

This is a story of medical art and crime; of murder and the workings of the law; of self-interest, detectives, and hypnotism; of pride, vain-glory, and hypocrisy; of climax, anti-climax, and finally life in-death by "sanatoxine," a deft preparation kept on hand by the unscrupulous hero to deprive himself of reason in order to escape the just punishment of his manifold misdeeds. Dr. Medjora, Spanish and beautiful, fascinating and mysterious, is left a raving maniac on the last page, after having disposed of one or two wives according to scientific methods, and been the prime mover in many schemes for his own aggrandizement. The "Modern Wizard" is intensely interesting, sometimes dramatic, and well written at intervals. It leaves the reader breathless and in a mixed frame of mind: why should an author of so much ability write such a book, and why should a reader of such intelligence read it? This question each must answer for himself.

railway surgeons were notoriously incompetent in neurological diagnosis, and that there was more need of railway neurology and medicine than of surgery.

We have no doubt, however, that the organization of railway surgeons into a national body will promote the material interests of the surgeons and render the work done by them more effective.

News of the Week.

Fear of Premature Burial.—The will of the late Mr. Edmund Yates contained a clause in which he expressed the desire that his jugular vein should be opened immediately after the physician had pronounced him dead, in order to prevent any possibility of his being buried alive. The medical man who performed the operation was to receive a fee of twenty guineas.

The Inheritance of Insanity.—Dr. G. Fielding Blandford, President of the Psychological Section of the British Medical Association, took as the subject of his opening address, "The Prevention of Insanity." One of the most important factors in the etiology of the disease, he said, is heredity. Sir Benjamin Ward Richardson has made the assertion that insanity is transmitted through the male line, but the speaker held that the reverse is the case, the taint passing through the female line rather than the male. He did not, however, insist so strongly on this point, holding that the safest rule was that no one, man or woman, who had had an attack of insanity, should marry.

Gift of Dr. Wilson Fox's Plates of Diseases of the Lungs to Medical Schools.—In a letter to *The Medical Press and Circular*, Drs. Sidney Coupland and W. R. Gowers direct the attention of the managers of medical schools in England, the Colonies, and America to the fact that there is a considerable number of the surplus sets of the colored plates of Dr. Wilson Fox's "Atlas of Diseases of the Lungs." These contain the most perfect representation of morbid states of the lungs ever produced. They will be of great value to medical schools, if framed and placed in the museum or post-mortem room. It is, therefore, proposed to give a set to each medical school the dean or manager of which desires it; a certain number will be reserved until October to give colonial medical schools an opportunity of obtaining them. Each set contains twenty-five colored plates. Brief descriptions can easily be prepared from the text of Dr. Fox's atlas and affixed to the plates. The cost of packing and transmission amounts to 1s. in the United Kingdom, 2s. 6d. for America and the Colonies. This sum should be sent, with the application, to Messrs. Mintern Bros., 84 Southampton Row, London, W. C.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty second Annual Meeting, held at Bristol, July 31 to August 4, 1894.

Special Report for the MEDICAL RECORD.

FIRST DAY, TUESDAY, JULY 31ST.

THE first general meeting of the sixty-second annual gathering of this Association was held on Tuesday morning, July 31st, and was numerously attended. The retiring President, Dr. George Hare Philipson, of Newcastle, occupied the chair. Having submitted the minutes, which were confirmed, he said the signing of those minutes was his last official duty. In vacating the chair he should avail himself of the opportunity of again expressing to his hearers his sense of the honor they had conferred upon him. The remembrance would be one of the happiest recollections of his life that he had occupied the chair, if he might be allowed to say it, of the greatest medical association in the world. He thanked them for the confidence which had been reposed in him, and for the support he had received in carrying out the duties of his office. He begged to offer them his congratulations upon the meeting in Bristol, and especially upon the choice of the distinguished physician who was to follow him in the presidency. It was now his pleasure to invite Dr. Fox to assume the office as President, and to offer him in his year of office every good wish that he might have a prosperous and happy year.

THE PRESIDENT ELECT remarked it was needless to say how very much obliged he was to them for the cordial reception of Dr. Philipson's introduction. He appealed to the members to be brief and to the point in their speeches.

DR. T. BRIDGWATER then moved a vote of thanks to Professor Philipson, and that he be elected a Vice president of the Association. DR. HOLMAN seconded, and the resolution was carried with applause.

The report of the Council was then presented. It referred to the pleasure that was felt in accepting the invitation to hold the annual meeting at Bristol. It was remarked that the city of Bristol was the headquarters, with Bath, of one of the oldest and most active branches of the Association, and it was interesting to note that the first anniversary meeting of the Provincial Medical and Surgical Association, now the British Medical Association, was held in Bristol in 1834, under the presidency of Dr. Andrew Carrick. It was on record that two hundred attended out of a total of three hundred and sixteen. Since the annual meeting last year an important change had occurred in the Association by the admission of medical women as members, and upward of forty had already been elected. The financial results had been successful. The revenue had been £35,367, or £1,223 more than last year, while the expenditure was £30,126, or £1,021 more than last year, leaving a surplus or profit of £5,150, which had since been invested. At the end of December the total excess of assets over liabilities was £55,906. The number of members on the books last year was 14,703. During the year 988 new members had been enrolled, 203 had died, 398 had resigned, leaving on the books 15,090. Among those members whose decease during the past year the Council deeply regretted to report were: Sir Andrew Clark, President of the Royal College of Physicians, whose many virtues and generous nature caused him to be universally mourned by the profession; Dr. Brown-Séquard, Dr. George Graham, an ex President of the Melbourne and Victoria Branch; Dr. James C. Philippo, the first President, and the founder of the Jamaica Branch—the first recognized colonial addition to the Association; and Surgeon-Major Parke, who received the Medal of Merit in 1890 for his brave conduct in the Stanley expedition.

DR. J. WARD COUSINS, President of the Council, moved the adoption of the report and financial statement. He said July 19, 1832, was a proud day for the medical profession, when their forefathers of the British Medical Association were assembled in the Worcester Infirmary to consider the proposal of Sir Charles Hastings in reference to the formation of the Provincial Medical Association. There were 140 present, and at the first annual meeting in Bristol, in 1833, there were 200 present. The next meeting held there was in 1863, and the Association then mustered 2,000 members. Now they came again with a roll of over 15,000, with an organization scattered all over the world, with Branches in India, Australia, New Zealand, Canada, South Africa, and the Colonies; and he need not tell them a most interesting incident was the admission of 41 lady doctors. He wished all lady graduates in medicine were members, and he firmly believed they would be in course of time. Referring to the penal clauses of the Medical Acts, he said they were practically moonshine. They could not get convictions. The Parliamentary Committee were anxious to amend the Medical Acts, as there was no doubt at the present time they could drive a coach-and-four through them. The Association desired to prevent the assumption of all sorts of letters which assumed medical titles. Then there was the University scheme, there was no doubt that required the supervision of the committee. The law relating to the employment of married women in factories was of the utmost importance, because the health of the future population of the country was connected with it. Among other questions alluded to was the sale of poisons. That was a move in the right direction. He owned, for his own part, he should like to see some such system as they had in France, under which the whole prescription of the proprietary medicine was on the label. Then he mentioned the Scientific Grants Committee, one of the objects of which was to promote research. For three research scholarships the Council selected gentlemen for a term of years, and large sums had been granted for scientific research. Dr. Cousins stated the Inebriates Committee had been very active. As to the medical charities, they would always be abused until human nature was pulverized and made over again.

SURGEON-MAJOR INCE then moved "That this meeting regrets the great and growing increase in the annual expenditure, as compared with the income of the Association; and suggests to the Council the expediency of a careful and substantial reduction thereof in all departments, especially in the matter of the editorial and office expenses, which appear out of all proportion to the needs and nature of the *British Medical Journal*." The Treasurer replied to the point raised in relation to the finances and regretted the personal allusions, maintaining that the editor had raised the *Journal* to the position of one of the best medical periodicals in the world. The editor also replied, maintaining that he had always endeavored to be impartial. He congratulated Surgeon Major Ince for contributing to the gayety of the meeting, and left the audience to judge whether he had given an example of the self-effacement he wished to apply to the editor.

DR. INCE said his object had been served by the discussion and he would withdraw the resolution.

MR. R. W. DOYNE, representing the Oxford Branch, moved an amendment to the report regretting that it contained no reference to the question of Medical Aid Associations, which had done so much injury by sweating members of the profession. The amendment was seconded by DR. MEAD, who said that very cruel cases had come before him as Secretary of the Medical Protection Association.

DR. COUSINS, then read the resolution of the Oxford Branch: "That, in the opinion of this meeting, medical men ought not to meet in consultation medical officers of Medical Aid Associations (as defined by the committee of the General Medical Council), and that the Branch Committee should bring the matter before the Central Council, and that they (the Central Council) be urged to bring the matter before the annual meet-

and the cunning leech of the past, and he maintained that those who were to practise the obstetric art should be as well trained in medicine and surgery as those practising any other branch of the profession.

Dr. Boxall agreed that the present state was really disgraceful. How, then, could it be improved? Could they get rid of the present midwives? If that could be, he thought that would be the best solution, but was afraid that was impracticable. The question was a national one, affecting the community at large. The select committee of the House of Commons took evidence from all sides, and they reported very distinctly in favor of registration. It was desirable to get the midwives under control, but how could that be accomplished without registration? That was not likely to injure the profession. It would not create a lot of midwives, they did not want a single extra one, would rather free themselves entirely. He hoped by such legislation as seemed practicable the condition of the poor might be improved, and the interests of the profession would be duly preserved.

Mr. George Brown said the way in which the committee of the House of Commons conducted their inquiry showed clearly that their sympathy was entirely with those who approved the registration, and he was surprised that their report was not even more decidedly in favor of the immediate passing of a measure for the registration of Sairey Gamp. It was absurd for members of Parliament to go behind the experience of a man like Dr. Atthill and recommend the legislature to sanction the registration of women after three months' education.

After some further discussion the resolution was put and carried by a majority of thirty four to thirteen, this being the total present, and the report as amended was then adopted.

Second Day, Wednesday, August 1st.

The President read out a list of visitors to the conference from various parts of the world, and also mentioned that representatives were present from many colonial Branches.

Dr. Ward Cousins stated that the Council received that morning a very large metropolitan deputation, headed by Dr. Russell Reynolds, inviting the Association to London for its next annual Congress. The Council recommended that they should accept the invitation, and he need not tell them that the Council would do all in their power to help the development of the meeting so as to give entire satisfaction, not only to the whole Association, but to their metropolitan associates. It would be a great satisfaction to know that they had selected as the President the President of the Royal College of Physicians. He moved that the invitation to hold the annual meeting for 1895 in London be accepted, and that Dr. Russell Reynolds be nominated as the President-elect. The President seconded, remarking he need hardly say they could not have a better President-elect, or a better place to meet in than London.

The Address in Medicine was then delivered by Sir Thomas Grainger Stewart, M D., Professor of Medicine in the University of Edinburgh, who said he did not propose to give an address on the general subject of medicine, but would select one special disease which had been much talked about among us of late, namely, the influenza, which, however, was no new epidemic, for Randolph, the ambassador from Queen Elizabeth to the Queen of Scots, described it accurately in a letter to "Her Grace" It was called "the new acquaintance," because it visited everybody. There were three types of the disease, the respiratory, the intestinal, and the nervous, while its complications and sequelæ were numerous. Some of the latter were purpura hæmorrhagica, vomiting, anæmia, gout, diabetes, cardiac symptoms, dropsy, pneumonia, phthisis, skin eruptions, sweating, affections of the urinary and reproductive systems, albuminuria hæmaturia, inflammatory symptoms as cystitis, and especially nervous, involving sight, hearing, and smell, sometimes increasing the power of these senses, but more usually decreasing them. We had considerably increased our knowledge of the histology of the disease. It had one essential cause, the Pfeifferian bacillus, which was always present and was never found in any other complaint. The result of inoculation with the cultivated virus was unsatisfactory, for no animal, except man, was affected by this micro organism, not even the monkey.

This bacillus will only live in the presence of hæmatoglobin. It does mischief in many ways, but chiefly by means of the poisonous products it sets up in the system. Possibly it provided a nidus in which other poisons found a chance of ready development at a time when the power of resistance of the patient was diminished, for exhaustion favors the growth of micro-organisms. Some white rats were inoculated with the bacillus of anthrat, half their number were placed in a cage and forced to work the tread-mill, the others were allowed to rest; the former developed the disease, the latter escaped.

Two organisms coexisting in the same subject may diminish the action of one or both; as they may increase it. The bacillus of tubercle when associated with the gonococcus found in green pus renders the disease of phthisis much more formidable.

Faulty innervation is at the bottom of heart and stomach troubles following influenza. The malnutrition of the tissues causes a poisoning of the nerves.

Causation of influenza is obscure; it was once thought to be propagated through the air. H.M.S. Stag was coming up the Channel, when a man was taken suddenly ill, and in twenty-four hours over one hundred men were laid down with the influenza. No similar case has since been recorded and no one takes the disease who has not come in contact with someone else who had it. It multiplies with extraordinary rapidity, so that in twenty-four hours a whole community may be affected.

The life-history of the influenza bacillus is peculiar—it will not live in water, which is good news for the teetotallers. It cannot bear drying and must be kept moist like some people. (Laughter.) The disease might be stamped out by isolating those affected. At all events, delicate people should not frequent crowded schools, theatres, or churches. Menthol and guaiacol will destroy the bacillus, or at least considerably diminish its activity; the mode of administering is by laryngeal injection, which is quite simple when you have found out the way to do it. Phthisical people are the best subjects for the experiment. The victim should yield at once—off to bed and take care of yourself.

Dr. F. Roberts proposed, and Dr. Shingleton Smith seconded, a vote of thanks to the lecturer, the former declaring that he was deeply interested by the assurance that the bacillus will not live in, and cannot be propagated by, water; he also congratulated him upon the honor the Queen had bestowed upon him.

Sir T. G. Stewart, in replying, said there was an old Scotch proverb to the effect that the best mirror is the eye of a friend.

The Middlemore Prize.—The President announced that the Middlemore Prize for 1891 had been awarded to Mr. Edward Treacher Collings, F.R.C.S., L.R.C.P., who, however, was travelling in Persia.

Dr. Ward Cousins explained that the prize was £50 interest on a sum of money left by the late Mr. R. Middlemore, of Birmingham, for the best essay on any subject in ophthalmology, medicine, or surgery.

Third Day, Thursday, August 2d.

Address in Surgery.—Mr. Greig Smith, Professor of Surgery in the University College, Bristol, then delivered the address in surgery, taking as his subject, "The Art of the Surgeon."

After gracefully acknowledging the honor paid to Bristol and himself in his selection for this duty he said

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-second Annual Meeting, held at Bristol, July 31 to August 4, 1894.

Special Report for the MEDICAL RECORD.

FIRST DAY, TUESDAY, JULY 31ST.

THE first general meeting of the sixty-second annual gathering of this Association was held on Tuesday morning, July 31st, and was numerously attended. The retiring President, Dr. George Hare Philipson, of Newcastle, occupied the chair. Having submitted the minutes, which were confirmed, he said the signing of those minutes was his last official duty. In vacating the chair he should avail himself of the opportunity of again expressing to his hearers his sense of the honor they had conferred upon him. The remembrance would be one of the happiest recollections of his life that he had occupied the chair, if he might be allowed to say it, of the greatest medical association in the world. He thanked them for the confidence which had been reposed in him, and for the support he had received in carrying out the duties of his office. He begged to offer them his congratulations upon the meeting in Bristol, and especially upon the choice of the distinguished physician who was to follow him in the presidency. It was now his pleasure to invite Dr. Fox to assume the office as President, and to offer him in his year of office every good wish that he might have a prosperous and happy year.

THE PRESIDENT ELECT remarked it was needless to say how very much obliged he was to them for the cordial reception of Dr. Philipson's introduction. He appealed to the members to be brief and to the point in their speeches.

DR. T. BRIDGWATER then moved a vote of thanks to Professor Philipson, and that he be elected a Vice president of the Association. DR. HOLMAN seconded, and the resolution was carried with applause.

The report of the Council was then presented. It referred to the pleasure that was felt in accepting the invitation to hold the annual meeting at Bristol. It was remarked that the city of Bristol was the headquarters, with Bath, of one of the oldest and most active branches of the Association, and it was interesting to note that the first anniversary meeting of the Provincial Medical and Surgical Association, now the British Medical Association, was held in Bristol in 1834, under the presidency of Dr. Andrew Carrick. It was on record that two hundred attended out of a total of three hundred and sixteen. Since the annual meeting last year an important change had occurred in the Association by the admission of medical women as members, and upward of forty had already been elected. The financial results had been successful. The revenue had been £35,367, or £1,223 more than last year, while the expenditure was £30,126, or £1,021 more than last year, leaving a surplus or profit of £5,150, which had since been invested. At the end of December the total excess of assets over liabilities was £55,906. The number of members on the books last year was 14,703. During the year 988 new members had been enrolled, 203 had died, 398 had resigned, leaving on the books 15,090. Among those members whose decease during the past year the Council deeply regretted to report were: Sir Andrew Clark, President of the Royal College of Physicians, whose many virtues and generous nature caused him to be universally mourned by the profession; Dr. Brown-Séquard, Dr. George Graham, an ex President of the Melbourne and Victoria Branch; Dr. James C. Philippo, the first President, and the founder of the Jamaica Branch—the first recognized colonial addition to the Association; and Surgeon-Major Parke, who received the Medal of Merit in 1890 for his brave conduct in the Stanley expedition.

DR. J. WARD COUSINS, President of the Council, moved the adoption of the report and financial statement. He said July 19, 1832, was a proud day for the medical profession, when their forefathers of the British Medical Association were assembled in the Worcester Infirmary to consider the proposal of Sir Charles Hastings in reference to the formation of the Provincial Medical Association There were 140 present, and at the first annual meeting in Bristol, in 1833, there were 200 present. The next meeting held there was in 1863, and the Association then mustered 2,000 members. Now they came again with a roll of over 15,000, with an organization scattered all over the world, with Branches in India, Australia, New Zealand, Canada, South Africa, and the Colonies; and he need not tell them a most interesting incident was the admission of 41 lady doctors. He wished all lady graduates in medicine were members, and he firmly believed they would be in course of time. Referring to the penal clauses of the Medical Acts, he said they were practically moonshine. They could not get convictions. The Parliamentary Committee were anxious to amend the Medical Acts, as there was no doubt at the present time they could drive a coach-and-four through them. The Association desired to prevent the assumption of all sorts of letters which assumed medical titles. Then there was the University scheme, there was no doubt that required the supervision of the committee. The law relating to the employment of married women in factories was of the utmost importance, because the health of the future population of the country was connected with it. Among other questions alluded to was the sale of poisons. That was a move in the right direction. He owned, for his own part, he should like to see some such system as they had in France, under which the whole prescription of the proprietary medicine was on the label. Then he mentioned the Scientific Grants Committee, one of the objects of which was to promote research. For three research scholarships the Council selected gentlemen for a term of years, and large sums had been granted for scientific research. Dr. Cousins stated the Inebriates Committee had been very active. As to the medical charities, they would always be abused until human nature was pulverized and made over again.

SURGEON-MAJOR INCE then moved "That this meeting regrets the great and growing increase in the annual expenditure, as compared with the income of the Association; and suggests to the Council the expediency of a careful and substantial reduction thereof in all departments, especially in the matter of the editorial and office expenses, which appear out of all proportion to the needs and nature of the *British Medical Journal*." The Treasurer replied to the point raised in relation to the finances and regretted the personal allusions, maintaining that the editor had raised the *Journal* to the position of one of the best medical periodicals in the world. The editor also replied, maintaining that he had always endeavored to be impartial. He congratulated Surgeon-Major Ince for contributing to the gayety of the meeting, and left the audience to judge whether he had given an example of the self-effacement he wished to apply to the editor.

DR. INCE said his object had been served by the discussion and he would withdraw the resolution.

MR. R. W. DOYNE, representing the Oxford Branch, moved an amendment to the report regretting that it contained no reference to the question of Medical Aid Associations, which had done so much injury by sweating members of the profession. The amendment was seconded by DR. MEAD, who said that very cruel cases had come before him as Secretary of the Medical Protection Association.

DR. COUSINS, then read the resolution of the Oxford Branch: "That, in the opinion of this meeting, medical men ought not to meet in consultation medical officers of Medical Aid Associations (as defined by the committee of the General Medical Council), and that the Branch Committee should bring the matter before the Central Council, and that they (the Central Council) be urged to bring the matter before the annual meet-

and the cunning leech of the past, and he maintained that those who were to practise the obstetric art should be as well trained in medicine and surgery as those practising any other branch of the profession.

Dr. Boxall agreed that the present state was really disgraceful. How, then, could it be improved? Could they get rid of the present midwives? If that could be, he thought that would be the best solution, but was afraid that was impracticable. The question was a national one, affecting the community at large. The select committee of the House of Commons took evidence from all sides, and they reported very distinctly in favor of registration. It was desirable to get the midwives under control, but how could that be accomplished without registration? That was not likely to injure the profession. It would not create a lot of midwives, they did not want a single extra one, would rather free themselves entirely. He hoped by such legislation as seemed practicable the condition of the poor might be improved, and the interests of the profession would be duly preserved.

Mr. George Brown said the way in which the committee of the House of Commons conducted their inquiry showed clearly that their sympathy was entirely with those who approved the registration, and he was surprised that their report was not even more decidedly in favor of the immediate passing of a measure for the registration of Sairey Gamp. It was absurd for members of Parliament to go behind the experience of a man like Dr. Atthill and recommend the legislature to sanction the registration of women after three months' education.

After some further discussion the resolution was put and carried by a majority of thirty four to thirteen, this being the total present, and the report as amended was then adopted.

Second Day, Wednesday, August 1st.

The President read out a list of visitors to the conference from various parts of the world, and also mentioned that representatives were present from many colonial Branches.

Dr. Ward Cousins stated that the Council received that morning a very large metropolitan deputation, headed by Dr. Russell Reynolds, inviting the Association to London for its next annual Congress. The Council recommended that they should accept the invitation, and he need not tell them that the Council would do all in their power to help the development of the meeting so as to give entire satisfaction, not only to the whole Association, but to their metropolitan associates. It would be a great satisfaction to know that they had selected as the President the President of the Royal College of Physicians. He moved that the invitation to hold the annual meeting for 1895 in London be accepted, and that Dr. Russell Reynolds be nominated as the President-elect. The President seconded, remarking he need hardly say they could not have a better President-elect, or a better place to meet in than London.

The Address in Medicine was then delivered by Sir Thomas Grainger Stewart, M D., Professor of Medicine in the University of Edinburgh, who said he did not propose to give an address on the general subject of medicine, but would select one special disease which had been much talked about among us of late, namely, the influenza, which, however, was no new epidemic, for Randolph, the ambassador from Queen Elizabeth to the Queen of Scots, described it accurately in a letter to "Her Grace" It was called "the new acquaintance," because it visited everybody. There were three types of the disease, the respiratory, the intestinal, and the nervous, while its complications and sequelæ were numerous. Some of the latter were purpura hæmorrhagica, vomiting, anæmia, gout, diabetes, cardiac symptoms, dropsy, pneumonia, phthisis, skin eruptions, sweating, affections of the urinary and reproductive systems, albuminuria hæmaturia, inflammatory symptoms as cystitis, and especially nervous, involving sight, hearing, and smell, sometimes increasing the power of these senses, but more usually decreasing them. We had considerably increased our knowledge of the histology of the disease. It had one essential cause, the Pfeifferian bacillus, which was always present and was never found in any other complaint. The result of inoculation with the cultivated virus was unsatisfactory, for no animal, except man, was affected by this micro organism, not even the monkey.

This bacillus will only live in the presence of hæmatoglobin. It does mischief in many ways, but chiefly by means of the poisonous products it sets up in the system. Possibly it provided a nidus in which other poisons found a chance of ready development at a time when the power of resistance of the patient was diminished, for exhaustion favors the growth of micro-organisms. Some white rats were inoculated with the bacillus of anthrat, half their number were placed in a cage and forced to work the tread-mill, the others were allowed to rest; the former developed the disease, the latter escaped.

Two organisms coexisting in the same subject may diminish the action of one or both; as they may increase it. The bacillus of tubercle when associated with the gonococcus found in green pus renders the disease of phthisis much more formidable.

Faulty innervation is at the bottom of heart and stomach troubles following influenza. The malnutrition of the tissues causes a poisoning of the nerves.

Causation of influenza is obscure; it was once thought to be propagated through the air. H.M.S. Stag was coming up the Channel, when a man was taken suddenly ill, and in twenty-four hours over one hundred men were laid down with the influenza. No similar case has since been recorded and no one takes the disease who has not come in contact with someone else who had it. It multiplies with extraordinary rapidity, so that in twenty-four hours a whole community may be affected.

The life-history of the influenza bacillus is peculiar—it will not live in water, which is good news for the teetotallers. It cannot bear drying and must be kept moist like some people. (Laughter.) The disease might be stamped out by isolating those affected. At all events, delicate people should not frequent crowded schools, theatres, or churches. Menthol and guaiacol will destroy the bacillus, or at least considerably diminish its activity; the mode of administering is by laryngeal injection, which is quite simple when you have found out the way to do it. Phthisical people are the best subjects for the experiment. The victim should yield at once—off to bed and take care of yourself.

Dr. F. Roberts proposed, and Dr. Shingleton Smith seconded, a vote of thanks to the lecturer, the former declaring that he was deeply interested by the assurance that the bacillus will not live in, and cannot be propagated by, water; he also congratulated him upon the honor the Queen had bestowed upon him.

Sir T. G. Stewart, in replying, said there was an old Scotch proverb to the effect that the best mirror is the eye of a friend.

The Middlemore Prize.—The President announced that the Middlemore Prize for 1891 had been awarded to Mr. Edward Treacher Collings, F.R.C.S., L.R.C.P., who, however, was travelling in Persia.

Dr. Ward Cousins explained that the prize was £50 interest on a sum of money left by the late Mr. R. Middlemore, of Birmingham, for the best essay on any subject in ophthalmology, medicine, or surgery.

Third Day, Thursday, August 2d.

Address in Surgery.—Mr. Greig Smith, Professor of Surgery in the University College, Bristol, then delivered the address in surgery, taking as his subject, "The Art of the Surgeon."

After gracefully acknowledging the honor paid to Bristol and himself in his selection for this duty he said

that former orators had chosen to sing pæans on our victories over science and glorified scientific heroes It was his intention on this occasion to leave science alone and deal with the art, and how we trained men to practise it. What was a surgeon? A stranger might judge from a study of door plates that there was no difficulty in answering; but the word "Surgeon" on a door usually meant that its possessor was capable of all branches of the healing art except surgery. The surgeon in these days of high-sounding titles was almost alone in following a craft called "handwork" whose title was needlessly humble.

The surgeon was first and foremost a physician. In person or by proxy he must lean on medicine. Besides medical training he must have special education in his handicraft. In old times the surgeon was the slave of the physician, later his enemy, to day his equal and helper. Their rivalry was now a goodly and a wholesome one. Among other arts and crafts surgery was unique in the breadth of its foundation on science. A surgeon must know something of all the sciences, a good deal of a few, and everything of two or three.

Was all our display of knowledge genuine? Examiners seemed to have their doubts, so fearful were they apparently that the student's knowledge might trickle away unless he were annually examined. When was the importation of new subjects into the curriculum to stop? The burden was becoming steadily heavier to bear. Should we cast off some of it as cumbersome or useless? Some said that we have too much anatomy, that it is useless to the practical surgeon, and that physiology was unstable and uncertain, that the young physiologist gives a dose of castor-oil, on much the same principles that his grandmother acted on. Pathology they said was the science of too late. These men were as honest as their opponents. From that very rostrum their views had been proclaimed. He ventured to differ. If asked, "Are we to lower surgery so that brains may not be strained?" he would answer, "Let surgery rise if brains fall!" He would not cast away anything, but he would select, rearrange, and raise, and have more anatomy, physiology, and more pathology.

The end of culture for the multitude seemed to be to nibble at science, dabble at art, and drivel over the glorious advances of the century. Surgery tolerated no dawdling or dilletanteism. The surgeon's knowledge must be real and thorough and practical, and he must carry it with him. He must have the real knowledge of the artist begotten of personal labor and not of cribs and mnemonics. That surgeon's armor was weakest at vulnerable points who was not protected by a complete panoply of anatomical knowledge. The complete surgeon must not cease to learn anatomy in his lifetime. Only the other day the attention devoted to the vermiform appendix had rendered our knowledge of its anatomy more perfect. Centuries of observation by the morphologist were not equal for our purposes to the few months' work of the practical surgeon. No honest surgeon dare let himself remain ignorant of any new pathological or physiological fact that might bear on his work. Bacteriology was of supreme importance, and we dare not stop anywhere in our studies so long as knowledge advanced.

There was real danger that the claims of science might injure the art of surgery. It was a pity that science should so often kill art. Certainly in surgery there was no reason for this, but science and art could flourish together.

The art of the surgeon might be viewed from two aspects; one side might be called mechanical, the other was closely allied to a fine art. Easily learnt as the mechanical side was it was worthy of being taught, and it would be good for most surgeons to spend a month or two in a mechanic's workshop. In respect of technical skill in handling, he would place surgeon's tools on a level with the sculptor's spatula or chisel, or only a little higher—they were mere accessories in the work of the brain-compelled hands.

The other side of the craft he would venture to compare with that which produced works of art. This side was far the most important. The highest part of surgical fine art—for surgery was nothing less—was braincraft uttered through the fingers, not mere dexterity or cunning. The finger-surgeon began at the wrong end, he ought to have been a button maker. The important sense of touch—the only one in which man excelled the lower animals—was trained through the intellect as much as the fingers, and was aided by other senses, especially sight.

There were no limits to the demands made on the surgeon's tactile powers. Touch to the surgeon was what hearing was to the physician. But it was always the intellect that interpreted. It was as true now as twenty centuries ago that "'Tis mind that sees and mind that hears; all other things are deaf and blind."

The sculptor and the surgeon both dealt with the human body. Each art demanded from its votaries absolute fidelity to form; ignorance led to grief in both. Their ways of working were also alike. In each the true artist went as far as necessary at once without trifling. The surgeon who was not an artist was good at some details, but not in all, and lacked a sense of true proportion.

The world lost a great surgeon in Leonardo da Vinci, and a great artist in Sir Charles Bell. What was the teaching of this art of surgery? There was no real teaching of the art of surgery in this country. We had to teach ourselves by experience alone. The young sculptor might with impunity make and break figures, but the young surgeon was not supposed to damage or destroy human beings.

Artist and craftsmen learnt their work with a master to correct their faults. Surgeons alone were unassisted in this way in their art, although in his science the student had guidance enough. Operative surgery on the dead body was useful and indispensable, but it was only a step toward operating. The art must be taught to the young surgeon while actually operating, and his mistakes pointed out and his successes commended. What would they not give now to have a Liston or a Syme at their elbows to teach them? To imagine Liston, trained as he was in the cruel and exacting school of preanæsthetic days, having before him our science was to realize the ideal surgeon-artist.

Apprenticeship or pupilage would do something for surgery, but we needed personal teaching in high art by competent masters, as was done in medicine and obstetrics.

The state would only help those who helped themselves. Let us do so, and we might one day seek for a Royal Academy of Surgery, and a school with teachers attached.

One of the great surgeons of five hundred years ago and more wrote, "Knowledge is created by additions, the same man cannot lay the foundation and perfect the superstructure. We are as children carried on the neck of a giant; aided by the labors of our predecessors we see all that they have seen and something beyond." Let us in our love for the new science not forget the old art. Let us graft our new truths on the old stock that they may long live and flourish.

Mr. Reginald Harrison moved a vote of thanks to Professor Greig Smith for his interesting address, and said the resolution only inadequately expressed the indebtedness of the Association.

Mr. Nelson Dobson, of Clifton, in seconding the resolution, said it was a peculiar privilege to do so on that occasion of a large assembly thanking his neighbor and friend. He further expressed the gratification of his brethren who practised in the neighborhood that one of them should have been chosen for this honorable distinction. The good old city of Bristol, he said, had made the name of Smith famous in surgical history: 'Dick' Smith and "Nat" Smith were familiar names until the present day, and he believed that Greig Smith would

also be remembered not only for his great achievements in surgery, but for the address he had just delivered.

The resolution was carried by acclamation, and briefly acknowledged by the Professor.

Most of the audience then dispersed, leaving only a few members to transact the formal business, which was at once entered upon.

This included the adoption of the Reports of the Scientific Grants Committee, of the Committee on Legislation for Inebriates, of the Therapeutic Committee, of the Medical Charities Committee, of the Committee on the Efficient Control of Railway Servants' and Mariners' Eyesight, of the Committee on the Examination of School Board Children, and of the Anæsthetics Committee.

(To be Continued.)

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 16, 1894.

SAMUEL B. W. MCLEOD, M.D., PRESIDENT, IN THE CHAIR.

The Paper Jacket, its History, and Applications.—DR. J. MARSHALL HAWKES read a paper upon this subject, and presented about a dozen illustrative cases. Since Ambrose Paré, in 1725, made his first jacket out of beaten brass, the ingenuity of many men had been devoted to the production of a jacket from material which should possess among other desirable qualities that of lightness. Wood, woven wire, plaster of Paris, and various other materials had been employed, but all were heavy with the exception of felt, and this was objectionable because of its thickness, tendency to break down, and to absorb the perspiration. Plaster was not only heavy, but it disintegrated, absorbed the perspiratory products, became offensive, was cumbersome, broke down, and became useless.

Dr. Hawkes came to make the paper jacket, after trying nearly all possible materials, in a case of injury to the vertebral column in 1887. He was unable to adapt a jacket which the patient could wear without undue suffering, until the use of paper was suggested by seeing some workmen making buckets of this material. He then suspended a patient, made a plaster mould on the nude body, and from this mould made a solid plaster cast, over which he constructed the paper jacket out of the best manilla paper. Successive layers of paper were put on and made to adhere by varnish, shellac, and various cement materials, until a thickness of about three thirty-seconds of an inch was obtained. The weight was scarcely fourteen ounces. According to the deformity to be treated, he padded the plaster cast at projecting points and cut it down at others on the opposite side, so that in time pressure reduced the projecting deformity and filled up the opposite cavity in the body of the growing subject. When the jacket was removed it was replaced during suspension. Many persons, especially girls, who refused to wear the plaster and other jackets or apparatus because of their clumsiness and weight, submitted to the application of the paper jacket early and with pleasure, because of its lightness, accurate fit, as if it were a corset, and because of the marked comfort which it afforded. It was well known that the weight of the jurymast or other support attached to the plaster jacket tended to break it down. The paper jacket being very strong, easily withstood the strain. Dr. Hawkes knew of no disease of the spinal column to which it was not applicable. It was important that it extend well down over the hip, say to the inferior spinous process, else the superincumbent weight of the body would cause pressure pain along the lower border. The importance of a snug, light, well-fitting, strong jacket, the wearing of which would not be objectionable to the most fastidious patient, was shown by the fact than an eminent surgeon had estimated that four per cent. of the population had some defect of the spinal column. Among the patients shown by the author were some of sensitive spine in neurotic subjects, railroad spine, and deformities from other injuries, lateral curvature, etc. None with Pott's disease happened to be present.

DR. A. B. JUDSON being requested to open the discussion, said: The management of these cases is the cause of anxiety, because the patient and his friends do not readily recognize the difference between lateral curvature, which may persist without interfering with a long and useful life, and Pott's disease, which is a destructive process in itself and exposes the patient to the risk of abscesses, paraplegia, greatly reduced stature, and serious deformity. The apparatus shown is admirable and of value in the treatment of certain cases, but in Pott's disease I would prefer an apparatus which enables us to apply adjusted and regulated pressure directly to the projection in an antero-posterior direction. Pott's disease is, with the exception of malignant disease, the most serious affection which can attack the skeleton. In itself the morbid process is curable, as is seen when it occurs in the ankle, the knee, and the hip. It is noticeable that the disease is more manageable in the smaller joints, evidently for a mechanical reason. The muscles are more able to arrest motion, and fixative apparatus is more efficient if the portion of the body lying beyond the diseased joint is of small size. If the hip joint or the spinal joints are in the acute stage of disease they are unavoidably disturbed by motions in other parts of the body, but a digital joint, for instance, may easily be kept motionless and undisturbed while violent motions are made in other parts of the body. It is this mechanical disadvantage, suffered by the carious vertebræ, which makes this disease almost malignant in its persistence. With this in view we must admire the zeal which Dr. Hawkes has infused into his work. In this way alone can the details, which are so large a part of all orthopedic work, be properly attended to. In fact the personal element is as important as the selection of a form of apparatus.

DR. VON DONHOFF thought the claims made for the paper jacket were well based. So far as scoliosis was concerned, there was a tendency for it to go on increasing in spite of mechanical treatment until nature arrested it. He thought Dr. Vance, of Louisville, was first to use the suspension apparatus. Dr. von Donhoff had come to regard suspension as dangerous, and therefore applied the jacket on a kind of hammock, in the horizontal position. He believed he had himself first used paper, 1874 or 1875.

DR. NEWLAND expressed the opinion that the more nearly one left the patient alone the greater would be his success in the treatment of curvature of the spine. Where a brace was called for the paper jacket would prove useful, but it lacked some of the advantages pertaining to aluminum.

DR. MILLIKEN preferred the iron brace, but since patients could not always be seen frequently, the plaster jacket had found a place. If one could prevent further deformity he would do well. He thought Dr. Bryan, a former Bellevue interne, first used plaster in this country. He preferred putting on jackets in the horizontal position.

DR. BROTHERS thought aluminum wire would come to be used for jackets in preference to other material.

DR. JUDSON remarked that Dr. Benjamin Lee, of Philadelphia, had used suspension before the date mentioned by Dr. von Donoff as the time when Dr. Vance first employed it, and Dr. Lee said he got the idea from Dr. John K. Mitchell, of Philadelphia.

DR. HAWKES said, in closing, that he would not put an iron brace on a child under any circumstances. He did not believe any extension of the spine could be got by placing the patient in the horizontal position. He had never seen danger or injury from suspension. That actual diminution of deformity had been effected was shown by the successive casts.

To say to a patient that her only hope lay in nature arresting further progress of the deformity, and then ask for a fee, reminded him of a picture in a comical paper, representing a bruised and dilapidated individual in the presence of a soothsayer who, having read in his past history that he had met with some accident, and predicted that he was to fall heir to a hundred thousand dol-

lars, extended his hand with the remark, "Two dollars, please."

Quinine Amaurosis.—Dr. J. Herbert Claiborne read a paper in which he described a case of quinine amaurosis, mentioned the rarity of the affection and the symptoms usually accompanying the condition. There were about fifty-five cases on record. His own case was seen with his father in the South. The eyes were examined also by Dr. Knapp. The man had been taking considerable quinine, and on one occasion, in order to prevent recurrence of symptoms and assure rest, he swallowed nearly a handful of two-grain quinine pills. Following which was blindness which had persisted since, or about three years. There had been only sufficient improvement to enable the patient to see slightly by reflected light, less well by direct or strong light.

The author reached the following conclusions with regard to quinine amaurosis: 1, Quinine in toxic doses may produce blindness; 2, the toxic dose is distinctly indeterminate; 3, the duration of the amaurosis varies greatly; 4, the field of vision remains contracted; 5, the central vision usually returns to normal; 6. there is color-blindness at first, color perception being ultimately restored in the central field; 7, the ophthalmoscopic picture is that of white atrophy; 8, experiments on dogs show that there is atrophy of the entire optic tract; 9, the same experiments show that the cells of the cuneus are probably not affected; 10, treatment is of no avail.

Dr. Claiborne's case was the severest on record. The trouble with hearing had quite disappeared.

The discussion was participated in by Drs. Hepburn, Van Fleet, Meeks, and the author. Dr. Hepburn thought the most curious point in the case related was better perception of light by reflected than by direct light. The affection seemed to be peripheral, but whether the toxic agent acted directly upon the nerve or through the circulatory system was a question.

Ligation of Uterine Artery for Control of Hemorrhage in Tumors.—Dr. A. H. Goelet presented certain gynecological instruments, and illustrated by drawing ligation of the circular artery of the uterus for control of hemorrhage due to tumors of the uterus, after the manner practised by Martin, of Chicago. Dr. Goelet thought he had done this operation before Dr. Martin.

The only danger was in tying the ureter and in sepsis. Confinement was from one to two weeks.

Special Committee to State Constitutional Convention.—On motion of Dr. Frank Ferguson, the President was empowered to appoint a special committee of five to act with like committees appointed by other medical societies, for the purpose of looking after matters medical before the approaching State Constitutional Convention.

Dr. Charles J. Proben presented a specimen of tubercular dachtylitis, Dr. Biggs having confirmed the diagnosis; also a specimen of broncho-pneumonia from a child.

Stated Meeting, May 21, 1894.

Samuel B. W. McLeod, M.D., President, in the Chair.

The Medical Department of the National Guard, its Status in Two Decades.—Dr. Joseph D. Bryant, Surgeon-General of the National Guard of the State of New York, spoke of the status of the medical department ten years before and ten years since 1884. The National Guard was composed of the military and naval service, all told of about fourteen thousand men, fifteen thousand being the legal limit. There were about five thousand men in New York City, three thousand in Brooklyn, twenty-five hundred in Albany and the country towns, and about the same number in Buffalo and surrounding counties. The National Guard served two important purposes, viz.: to serve the State in case of riots, and to form the nucleus of an army in case of war. The naval reserves numbered four or five hundred. The men enlisted for five years and drilled once a week for seven months a year.

Medical Department.—This was made up of the surgeon-general, surgeons major, and assistant surgeons of the rank of captain or lieutenant, in all about ninety medical men. Then there was a hospital corps of instructed non-medical men, and hospital stewards, numbering about one hundred and fifty-six men.

Briefly stated, the duties of the medical officers during ten years, prior to 1884, were simply to appear on dress parade and to add to the social enjoyment of the officers at whose pleasure they were appointed. They signed papers in a perfunctory way.

A change has been effected since 1884, and to day the duties of the medical officers, from the surgeon-general down, were much more onerous. Scrutiny was not exercised in the appointments, and while the commanding officer could name a doctor whom he would like to have appointed his power ended there. Those selected had to appear before a medical examining board, and not a few of them had failed to pass the examination. The approval of the surgeon-general was requisite after the candidate had been recommended by the examining board. Their duties, when appointed, were medical and educational. They had to examine every recruit and to look after the health of the troops. The educational duties were to give instruction to the hospital corps in the matter of giving first aid to the injured, etc. The hospital stewards were formerly undertakers, butchers, etc., while to-day they were required to be educated in pharmacy. Formerly there was no regular hospital or ambulance corps, men acting only for the occasion, while at present a certain number were appointed for this position for the whole period of five years, and received special instruction in the care of the wounded. At the end of the period, if they passed the examination, they were given a certificate and two badges, one being that of the Red Cross.

They had thus built up in this State, as had been done in a few others, a complete system corresponding to that in the regular army.

After some remarks upon Dr. Bryant's paper by Drs. N. H. Henry, A. M. Jacobus, Brothers, and the author, the Society listened to the reading of the second paper of the evening, by Dr. John G. Coyle, on

Membranous Enteritis, with Report of a Case.—Dr. Coyle had found few cases reported, but believed the condition was often overlooked because of neglect to examine the stools. No fibres were found in the discharged membrane, it differing from diphtheritic enteritis in that regard. Some patients passed yards of membrane resembling tape-worm, for which it had sometimes been mistaken. The disease was chronic, attacks coming on for slight cause in those who were susceptible. The treatment related to diet, cleanliness by rectal enemata, and catharsis as might be indicated. There was little fever. His own patient was a woman, thirty-five years of age, who had at times suffered from great distention and rumbling in the abdomen, severe abdominal pains at the time of the attacks, headache, etc. The condition probably dated from 1885, since which time she had had attacks of dysentery, but membrane was discovered only the past year, when Dr. Coyle began to examine the stools, and since that time there had been discharge of non-fibrous membrane in three attacks.

Dr. Gessner Harrison had seen one case of membranous enteritis in a patient who supposed the cast was part of a tape-worm and brought it to him. She said her brother had been troubled in the same way.

In some closing remarks Dr. Coyle dwelt upon the importance of carefully examining the stools in gastro-intestinal troubles, just as one would examine the urine in suspected renal disease.

Dr. T. H. Manley reported as delegate to the International Medical Congress which recently met at Rome. He pronounced the meeting a success, scientifically and socially.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting April 11, 1894

GEORGE C. FREEBORN, M.D., PRESIDENT, IN THE CHAIR.

Carbolic Acid Poisoning.—DR. H. P. LOOMIS presented the following: A man was taken suddenly ill on the street and died before the ambulance reached him. The autopsy showed that death was due to carbolic acid poisoning. The specimens showed very well the extreme congestion and corrosion of the larynx and œsophagus. The tissues were very well preserved, although they had been kept in a cool place for about one week without any special preservative fluid.

Abscess of the Brain.—W. J——, thirty four years of age, was admitted to Bellevue Hospital in a somewhat stupid condition. He answered all questions in a loud voice. He had been complaining for two months previously of pain in the right side of the head and in the right ear, and there had been a discharge of pus from this ear for a short time, but it had ceased before his admission to the hospital. The day after admission he suddenly developed paralysis on the left side, which was more marked in the left arm. After a few hours the stupor became profound, and he died the following day. At no time was his temperature over 99° F. A diagnosis was not made during life. On removing the brain there was a peculiar yellowish appearance, but no evidence of an abscess until the brain was cut open. The brain, with the exception of an abscess in the temporal lobe on the right side, was normal, as were also the other organs of the body. The abscess in the temporal lobe was marked by a cavity about an inch and a half in diameter, and this cavity was filled with thick, greenish pus. The bones of the ear were cut open, and in the mastoid cells and the petrous portion of the temporal bone collections of pus were found. There was no meningitis—in other words, no extension by continuity. The sinus was thoroughly examined, but no thrombus was found. Cultures were made only from the abscess, and these showed the presence of the staphylococcus albus, the cladothrix, the bacillus liquefaciens, and a diplococcus resembling Fränkel's, but its exact character had not been positively determined.

Perforation of the Œsophagus of a "Sword swallower."—DR. LOOMIS also exhibited the diaphragm, œsophagus, and stomach from a man, thirty nine years of age, who had died within half an hour after admission to Bellevue Hospital. At the autopsy, on removing the sternum, the left pleural cavity was found to contain a large amount of dark liquid with little oil globules floating on top, and masses of what appeared to be fecal matter floating in it. The lung was compressed against the spinal column, and the heart was pushed over to the middle line. There was an odor of acetic and butyric acids in the liquid. Thinking that possibly the intestine had ruptured through the diaphragm and had become strangulated, it was next dissected out, and was found to be free throughout its entire extent. The diaphragm was then examined and found intact. The lung was next carefully removed, and was found to be completely atalectatic. After careful search it was found that the little finger could be passed into the left side of the œsophagus a little above the diaphragm; in other words, there had been a perforation of the œsophagus, leaving a clean cut, linear opening, 2 ctm. in length, extending down to the œsophageal opening in the diaphragm. There was no evidence of ulceration or infiltration. On examining the cardiac end of the stomach radiating lines were found around the œsophageal opening, which seemed to have resulted from injury. All three inner coats were gone, and the peritoneum laid bare. No other part of the stomach or œsophagus was injured in any way, and careful search throughout the entire alimentary tract failed to reveal the presence of any sharp pointed or sharp-edged body; in fact, no foreign body of any description was found. Subsequent inquiry showed that this man had been a sword-swallower, and had been performing almost up to the day of his death. Probably the injury had been inflicted by a sword.

Diverticula of the Sigmoid Flexure of the Colon.—DR. GEORGE P. BIGGS presented the specimen. It was removed from a woman, fifty five years of age, who died of chronic tuberculosis, chronic diffuse nephritis, and cirrhosis of the liver. About two inches above the brim of the pelvis there was a hard mass in the posterior wall of the sigmoid flexure of the colon, and on cutting into this from the outer surface a pocket was exposed which contained nearly one drachm of thick yellowish pus. It measured 2 ctm. × 1 ctm., the longer measurement corresponding with the axis of the gut. The tissues around this were distinctly indurated, although there was no localized peritonitis, the inflammation being entirely in the adipose tissue surrounding the sigmoid flexure. After some difficulty a small probe was passed through a small opening into the lumen of the gut. There were a number of other diverticula.

This condition of multiple diverticula in the colon, especially in the lower portion, would be found not to be uncommon, the speaker said, if careful search were made for it. These diverticula generally contained fecal matter. He had never before seen them inflamed as in this case, although there was no special reason why this should not occur.

DR. JAMES EWING said that he had recently seen two cases of anæmic colitis with marked ulceration, in which all the normal diverticula of the sigmoid flexure for about one foot were much dilated, so that they were capable of holding two or three drachms of fluid. They were not, however, inflamed.

Diphtheria and Pseudo-diphtheria Bacilli.—DR. WILLIAM H. PARK presented cultures and cover-glass "smears" of a number of varieties of diphtheria and pseudo diphtheria bacilli, and briefly alluded to the views that had been held by bacteriologists regarding the nature of these bacilli.

In 1888 Hofmann published the results of some investigations in which he stated that besides finding the diphtheria bacilli in cases of true diphtheria, he had found them in twenty-six out of forty five throats in which no diphtheria had existed. Some of these bacilli were shorter, thicker, and more regular in form than the Loeffler bacilli, and grew more readily on agar, the growth being both more luxuriant and whiter. Others, however, were in all respects identical with the Loeffler bacillus except that those from healthy throats were not virulent. He did not feel able to state whether or not these two forms were identical with the virulent diphtheria bacilli of Loeffler, or a different form of bacteria. Loeffler himself, and most German writers have considered them to be altogether a different form of bacteria, while Roux and Yersin, most Frenchmen, and some Germans have looked upon them as identical. Roux and Yersin in their studies on diphtheria gave careful attention to the relationship of the so called pseudo-diphtheria bacillus to the true one. The majority of the bacilli they studied were identical with the Loeffler diphtheria bacillus in growth, size, and form, and differed simply in not possessing virulence. Exceptionally they found bacilli which were shorter, grew somewhat more luxuriantly on agar and in broth, and at a somewhat lower temperature (20°–22° C.) than the true diphtheria bacillus. This latter quality was sometimes only acquired after the bacilli had grown some generations on artificial media. The changes in reaction in bouillon caused by the growth of the bacilli were the same as in the case of true bacilli, but change to acid, and later return to alkaline reaction was more rapid. It was noted that the non virulent bacilli were only present in small numbers in the throats, so that the serum tubes usually contained but one to four colonies.

In a hospital for children in Paris, where cases of diphtheria were occurring from time to time, cultures were made from forty-five throats, and non-virulent bacilli found in fifteen. In a village in France, by the

coast, where no diphtheria had been present for a long time, cultures were made from the throats of fifty nine children living in a school, and in twenty six of these non-virulent bacilli were found. In an examination of ten throats of attendants in a diphtheria hospital non-virulent bacilli were found once. Therefore in one hundred and fourteen healthy throats the bacilli were found seventy-two times. From these experiments they concluded that a bacillus similar in all essential characteristics with the diphtheria bacillus, except for its lack of virulence, was a fairly common inhabitant of the healthy throat.

With regard to its frequency in disease, it was noted twice in six children with mild sore throats, and five times in the throats of seven children in which the sore throat was complicated with measles. They found that the cultures of true cases of diphtheria could be distinguished from those from healthy and diseased throats by the fact that the cultures from true diphtheria contained a great number of colonies of the bacilli, while those in which non-virulent bacilli were present the colonies were very few, there never being more than from one to four present in one tube. This would be a valuable practical guide if it were only true.

The connection between the most virulent and the non-virulent bacilli is shown by the gradations in virulence of diphtheria bacilli. As a rule, the more severe the case the more virulent the bacilli were found to be. In cases which recover, the bacilli become less and less virulent as convalescence progresses. It has been found that throats recently the seat of diphtheria were more apt to contain the non virulent bacilli than were other throats. They regarded occasional slight differences in growth, shape, and staining as too slight and inconstant to separate the virulent form from the non-virulent. They regard a division founded upon the reaction to inoculation of the guinea-pig as an arbitrary one. It is well known that there exist bacilli which exhibit all grades of virulence in guinea-pigs, some causing certain death, some marked local changes, some temporary and slight œdema, and some causing no appreciable reaction whatever. They believe that in order to prove the two forms to be varieties of the same bacillus it is necessary to first derive the non-virulent form from the virulent, and secondly to derive the virulent form from the non-virulent. The first they have accomplished, but in the second they have failed.

When grown for a long time on agar a temporary loss of virulence occurs. When the bacillus is grown in broth through which a current of air is constantly passing, it is found that after two weeks the bacilli begin to lose their virulence, and at the end of four weeks they become harmless. A few days later the bacilli in the culture will die. Just prior to this time when all living bacilli produce non-virulent cultures, it has been found that some would produce virulent and others non-virulent cultures. When kept at 45° C. for three days the bacilli were found to possess many of the characteristics of the pseudo-bacilli. They were unable, however, to give virulence to those bacilli which produced in guinea-pigs no effect whatever. This was true both in those in which the loss of virulence had been acquired artificially, as in those in which it had occurred naturally.

Escherisch found in one city, out of seventy throats examined, non-virulent bacilli in two, and in another city, out of two hundred and fifty, they were present in eleven. In none of these was diphtheria present at the time of making the cultures. The animal inoculations were made from a forty eight hours' growth in glucose alkaline broth, and the quantity injected was equal to half per cent. of the weight of the guinea pig. With these precautions he never found any bacilli which had the characteristics of the diphtheria bacilli which did not prove virulent in guinea-pigs. The pseudo-bacilli were as described by Hofmann in some of his cases, viz., shorter, plumper bacilli, and of fairly uniform size. The growth on agar was more luxuriant, and in his cases whiter than the Loeffler bacilli. This investigator has also called attention to the fact that the pseudo-diphtheria bacilli show a tendency to lie in parallel rows on a cover-glass, while the Loeffler bacilli are collected together in a most confused manner. A further and most important difference was that the pseudo-diphtheria bacilli grown in litmus bouillon turned it blue after forty eight hours, while the true diphtheria bacilli produced acid, and turned the litmus red. There were no exceptions to this rule, so that where it was impossible to make animal inoculations he considered this would prove to be in all probability a certain guide in doubtful cases. With the true bacilli there was no relation observed between the amount of acid formed and the degree of virulence. He, too, found that in the milder cases, or during convalescence, the bacilli were apt to be less virulent, but to this rule there were many exceptions. This investigator concludes that since we have found constant cultural differences to exist between the true and pseudo-diphtheria bacillus, we can give the pseudo diphtheria bacillus no diagnostic value, and further, we do not find it a frequent inhabitant of the throat.

The speaker, continuing, said that if time permitted a more extended review of the results obtained by others, we would still more clearly be brought to believe that there are several varieties of bacilli grouped under this name of pseudo-diphtheria bacilli, for how otherwise could some observers affirm that the bacilli cause alkaline bouillon to become acid, while others equally good assert that it becomes alkaline; or that some should find them to be identical in all morphological and cultural characteristics with the Loeffler bacilli, while others find distinct and constant differences? Dr. Park said that in the large number of experiments carried out in the laboratory by Mr. Alfred L. Beebe and himself, they had met with numerous examples of all the forms described. Cultures from 330 non-diphtheritic throats gave, in 22, virulent Loeffler's bacilli; in 21, non-virulent characteristic bacilli; and in 28, Hofman's pseudo-bacilli.

Dr. Park then offered the following classification, and presented to the Society cultures in bouillon and on agar, and cover-glass smears representing each of these divisions:

1. Loeffler's Diphtheria Bacilli.—Found in cases of true diphtheria, and in persons brought in contact with them. They all produce the toxines described by Loeffler, Roux, Fränkel, and others. They are subdivided into, *a*, bacilli characteristic in growth, shape, and staining; and *b*, bacilli not characteristic, but still having the recognized slight variations only. All these produce acid in their growths in broth.

2. Probably Loeffler's Diphtheria Bacilli.—They agree with the above classes in every way except that they have no virulence when injected in animals, and do not produce the toxines. They are found in healthy throats.

3. Probably not Loeffler's Diphtheria Bacilli.—The growth on agar and serum is far more luxuriant than is ever seen with true bacilli. They first make the litmus cloudy, and then give the acid reaction. They are subdivided into, *a*. Shorter, plumper bacilli which usually stain evenly. They grow rather more quickly on agar, frequently give rise for the first twenty four hours to a cloudy broth, and give an alkaline reaction with litmus bouillon. (Probably a subdivision could be made here into those causing a luxuriant growth on agar, and those which do not do so, and which are plumper.) *b*. Bacilli shorter and plumper than is usual in Loeffler's bacilli, but taking a fairly characteristic stain. This third class is found in healthy throats, and more rarely with diphtheria bacilli in cases of diphtheria.

Dr. H. D. Chapin asked in regard to examinations made several weeks after dipntheria.

Dr. Park replied that if one followed them up for six weeks, they would be found to become less and less virulent while retaining their morphological appearances. He had not examined them after six weeks, but at this

time they were apparently in about the same condition as in children in whom they had been found, and yet who had not developed any symptoms of diptheria. The diagnosis was made chiefly on the stain, and the varied size and shape of the bacilli. These characters ranked next in diagnostic value to animal inoculations.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CHELSEA HOSPITAL—MEETING OF GOVERNORS—RESIGNATION OF STAFF—HEALTH CONGRESS IN LONDON—RECEPTION BY LORD MAYOR—SUCCESSFUL MEETING—WORKHOUSE BARRACK SCHOOLS—DEPUTATION TO GOVERNMENT—INQUIRY PROMISED—MASSAGE SCANDALS—THE BRITISH MEDICAL ASSOCIATION WEEK.

London, July 28, 1894.

The troubles of the Chelsea Hospital for Women are not yet over. On Tuesday last there was a special meeting of the Governors to consider the report of the Committee of Inquiry. Lord Cardigan took the chair, and announced that as far as practicable the recommendations would be carried out. He could not, however, see how the lay members of the Board could control the staff or even ascertain that their work was at all times properly carried on. They must depend for their knowledge on the medical members of the Board, and the staff were thus represented but did not form a majority of the Board, and his Lordship held that this was quite right, in which opinion most men of experience will probably concur.

It was announced that in order to give the Board and Governors a free hand in the reorganization of the hospital the staff had all resigned, but were willing to continue their services pending the appointment of their successors. Dr. Fenton, on behalf of the staff, accepted the recommendations of the committee and pointed out that Dr. Parkes had withdrawn the expression in his report as to the "justifiability" of certain operations. This expression, I remarked at the time, was certainly not a proper one from a medical officer of health, who could not pretend to any expert surgical knowledge. Dr. Fenton pointed out that although retracted by Dr. Parkes this is not so well known as it ought to be. In regard to the mortality, Dr. Fenton produced statistics showing that in the special departments of large general hospitals there had sometimes been even a higher death-rate. Thus, as an example, the rate in ovariotomy had varied in six hospitals between 4.3 and 22.2 per cent., and Chelsea did not reach this maximum in spite of its sanitary defects. This only shows that it is impossible to draw conclusions from a percentage calculated from a few cases. After the meeting the Board of Management held a sitting in order to proceed with the reconstitution of the hospital. I hear that they will proceed to elect a new staff. To me it seems they might well follow the example of the late staff and resign their position; for, after all, the Committee of Inquiry condemned the Board of Management, and if anyone should resign they should, and the Governors should proceed to a new election. But then, Governors are, as a rule, merely subscribers—only a few take a real interest in such things and leave the work to those who do. These give their services and have a claim for consideration in case of mistakes or neglect, and nothing worse is alleged. At the same time the medical staff equally give their services and are not responsible for management. But then the medical officers are the readiest scapegoats, and in every alleged abuse are sure to be blamed. Then they resign and others are only too anxious to jump into their shoes. This is the usual end of every hospital scandal.

The Health Congress has met this week in London. This meeting was arranged by the British Institute of Public Health at their Congress last year, which was held in the University of Edinburgh, when on the proposition of the Lord Mayor of London it was decided to meet this year in the metropolis. All the sanitary authorities in the kingdom were invited to send delegates, and nearly two thousand were appointed. On Wednesday they were received at King's College, by Dr. Littlejohn, President, and Sir C. Cameron, Vice-President. On Thursday there was a great meeting at the Mansion House, the Lord Mayor in the chair, supported by the sheriffs and other city officials in their robes of office.

Professor William R. Smith, the new President, having been installed read his address, which appropriately dealt with the question of the Local Government of London. Curiously enough, on the eve of the Congress, the *British Medical Journal* came out with a spiteful little article evidently intended to spoil the meeting. People asked each other what it meant. It was said that a number of men had withdrawn, and hinted that the Mansion House assembly would be a failure. It would have done the editor good to see how little his own personal withdrawal, so ostentatiously announced, affected the Congress. All sorts of comments are made, but no one seems to know or care much in what way the managers have trodden on the editorial corns, but it is suggested that there has been a lack of adulation toward the D.C.L. The *Journal* has at the same time done good by agitating about the barrack pauper schools, respecting which it got up a deputation to the President of the Local Governing Board, who promised some inquiry either by a royal commission or a select committee of the House of Commons. It is not impossible that such inquiry may be more extensive than asked for. If that be the case so much the better. We need full inquiry into our Poor Law system rather than investigations restricted to one or two cases at a time. The deputation which was received on Tuesday was a very influential one, representing all parties, and including women as well as men, a natural thing when the interests of children are concerned. Sir John Gorst introduced the deputation in a moderate speech which the minister listened to attentively and commended, but Mr. E. Hart was reminded that his controversial speech went beyond his brief. He certainly deserved the rebuke as the sensational statements he made were evidently intended for an outside audience. Mr. Shaw-Lefevre looked at the question as a grave one, and as he promised to bring it before his colleagues in the ministry with the view of appointing an inquiry, the object of the deputation was obtained.

Vice seems ever ready to raise its head in large communities. It is now asserted that some establishments for massage are only brothels in disguise. The papers are full of the subject, and *Truth* admits that its editor has been for months informed of the existence of "facts such as no decent person could contemplate without horror!" It is to be hoped that this new scandal—the most horrible of the many that have been exploited—may lead to such action as shall deliver us from this form of the social evil and some others with it.

London, August 4, 1894.

The centre of gravity of the profession, so to say, has been shifted to Bristol for most of the week. Some went off on Monday, especially officials, but most were content to take a morning train on Tuesday; while others waited till afternoon and so missed the first general meeting and the sermon, but were in good time for the sections, which only began work on Wednesday morning.

As your several reporters will furnish you with full accounts of both the general meetings and the sectional proceedings, I need only gather up in this letter some of the fragments of the more popular side of the week's doings.

The attractions to the general meetings are the addresses. At the conclusion of these, or, at any rate, after the vote of thanks, there is usually a stampede, only a

few enthusiastic members staying to transact formal business, or join in discussions of which notices have been given.

These discussions, however, are the only occasions on which discontent can be expressed with the council or officials. It is not to be wondered at that among so many members differences of opinion and dissatisfaction should be found, and it is well that expression should be given to such sentiments. I hear, however, that the officials would like to suppress them. The policy of sitting on the safety-valve is not a very safe one, and it is possible the officials may be convinced of this in an unpleasant manner if they do not take warning. The editor came in for the mingled manifestations of approval and disapproval to which he is accustomed, but he is too astute a person to push any further the considerable irresponsibility which he has managed to attain.

The exhibitors of the Museum gave a musical conversazione on Tuesday night, which was numerously attended by the residents as well as the profession; and then the evening's proceedings, a new feature, proved most successful. The band of the Royal Marine Artillery was especially engaged, and played through a lengthy programme of music which was thoroughly enjoyed. The general meeting not being over till late prevented an early attendance, but by 9.30 the guests arrived in large numbers. There was a little speaking and the buffet arrangements were on a most liberal scale, and great satisfaction was expressed.

As to the Annual Museum, the present display is perhaps the most attractive and comprehensive that has been seen. The fine hall was most effectively laid out, the stands uniformly placed with great taste, and novelties shown on all sides, many coming under the head of surgical instruments and appliances. One of the chief features of the show was located in a small room, and had been prepared by Messrs. Oppenheimer, Sons & Co., Limited, London, and was in charge of Dr. Sambon, who has collected one of the largest assortments of antiquities allied to medicine ever seen in England. He proceeded with his researches for many years on behalf of the Italian Government, and says he has found abundant proof that the ancients had a more accurate knowledge of human anatomy than is generally believed. This he asserts by showing many well-executed specimens of different parts of the human frame and its organs, in terra-cotta, which had been given as votive offerings to the deities, who were supposed to preside over the wells believed to possess curative powers. He has fine models of ears, eyes, fingers, and scalps, all of which he says were thrown into these wells by persons who sought relief from complaints affecting those parts of the body. These all date from the Roman period, and display great skill, as they were the work of ordinary potters. This is supplemented by some three hundred surgical instruments from the pre-Christian days down to the fifteenth century, so it will be gathered the show is intensely interesting. At another stand were shown an interesting collection of optical scientific instruments; then there were stands to show the many new departures in food and physic. Messrs. Ferris & Co. made their stand the most attractive in the hall. Drugs naturally form a large portion of the show, and they are supplemented by many special preparations. The collection of surgical instruments is most comprehensive. The ever-ready plaster caddy is also shown as being Messrs. Ferris & Co.'s specialty, for keeping all kinds of surgical dressings in perfect condi tion without waste, and always ready to hand.

On Wednesday evening, August 1st, a series of enjoyable entertainments took place at Clifton College. These were arranged by the President and Executive Committee, and will be long remembered as forming one of the leading social features of the Bristol Congress. It was numerously attended, and the performances of the Orpheus Glee Singers were much appreciated. These singers have a reputation which is not confined to Bristol; no one could have gone away dissatisfied, for the members of Bristol's great choir acquitted themselves admirably. At the end of the concert there was an organ recital, and late as the hour was before it began, very few of the guests left before it terminated. Supper was served in a large tent, and after partaking of it we went and paid a visit to the Zoölogical Gardens, which were charmingly illuminated during the entire evening. This most enjoyable conversazione was brought to a close by a display of fireworks closing with a set piece, "The Good Samaritan," which was a well carried-out pyrotechnic performance. Then God Save the Queen was played and we each retraced our ways to our various hotels.

At 11 o'clock on the same day there was a grand organ recital at the Colston Hall by the organist of the Bristol Cathedral; invitations were freely distributed and there was a large gathering. The programme was selected with a view to displaying the great compass of the organ, and in this was very successful. Moreover, the items were full of tune and finish and much appreciated.

I must not forget the opening ceremony of the Clifton Pump room and Spa, which was publicly inaugurated on August 1st by the Mayoress of Bristol, and has been undertaken and completed by Geo. Newnes, M.P. The magnitude of the work gave rise to difficulties, and would have sorely tried the patience of less resolute men than Mr. Newnes, as will be appreciated when it is explained that the whole site has been cut out bodily from a sloping limestone rocky garden, which was acquired as being the finest position in Clifton for the purposes contemplated. It well deserves its name, and stands out in bold relief upon Sion Hill, reflecting the greatest credit on the architect and engineers. On this occasion several speeches were made and an illuminated address was presented to Mr. Newnes. In the evening, at the invitation of Mr. Newnes, many persons enjoyed the dual pleasure of listening to an excellent concert at the Grand Spa and inspecting the splendidly appointed Pump room. Lovers of music were also catered for on several other occasions during the Congress.

On Thursday some five hundred members were entertained at a garden party at Ashton Court, but unfortunately the weather was very unfavorable; happily there was a winter garden and museum in which they could take refuge. Another garden party was also spoiled, but here again in-door provision was made for such an event, an organ recital and other entertainments being provided. During the meeting the National Temperance League gave a breakfast to a number of the members. The League has done this for several years, and their breakfast has become a feature of the annual gathering. On this occasion the breakfast was presided over for the first time by the President of the Association, Dr. Long Fox, who is himself an abstainer, and who in welcoming the guests said he thought their position as medical men, with reference to this question of temperance, was that of medical missionaries. (Hear, hear.) There were many ways of helping and encouraging the movement, and it was impossible to say that many of these ideas were not very useful indeed, because, as the mind of man was various, so the methods of man were various also. He was not there to cavil at any of these methods, as some might say that law was of little practical use unless the common-sense of the nation had been educated up to its reception as a national want; but the great principle of the National Temperance League, the good influence of one person upon another in this temperance cause, would meet all possible objections. (Hear, hear.) Great as was the influence exercised by temperate medical men, with the full knowledge they had of how harmful alcohol was to vitality, and how injurious it was to many organs of the body, the chance of turning a neighbor from the error of his ways was enhanced a thousandfold if the speaker were a total abstainer himself. (Applause.) They could do something in the way of removing the stones from the King's highway. Already one sixth of the population had shaken itself from the

hideous evil that tended to the destruction of the nation, and in the noble fight against drink, the cause of poverty, disease, and crime, the key note of that and all kindred societies, they might justly boast would include freedom from all excess. (Loud applause.) The other night Dr. Annie Cornall wished the cause every success, and said the movement was especially important in relation to women, because they had such influence in the home.

Speeches were also delivered by Professor Cameron, of Glasgow, Dr. Ridge, Dr. Mackenzie, of Belfast, Dr. Hughes, of Wales, and Dr. Norman Kerr. Mr. Robert Rae, the Secretary of the League, returned thanks, and said the work of the League among the members of the medical profession was the most successful they had ever undertaken.

I hear that the dinner was well attended, but I did not go, having partaken of as many of these entertainments as I care to. For I have found each one very much a replica of the rest. So also I was unable to take the trip around the docks, which I hear about a hundred members enjoyed.

SHORTHAND IN MEDICINE.

To the Editor of the Medical Record.

Sir: In order to promote the use of shorthand in medicine, it is desirable that a list should be compiled of all who use it. We would, therefore, ask each practitioner and student who is acquainted with phonetic shorthand, to send his name and address to Dr. Neil, Warneford Asylum, Oxford, England.

The preparation of a list of medical phonographers is intended as a preliminary step to such further measures for mutual encouragement and help as may appear advisable.

W. R. Gowers, M D , F.R.C.P.,
Edward B. Gray, M.D.,
James Neil, M.D.

NON VOLUIT NOCERE.

To the Editor of the Medical Record.

Sir: In my lecture "Non Nocere," delivered before the Eleventh International Congress, which you printed in your issue of May 19th, I referred to a case of idiocy with premature ossification of the cranial bones kindly reported to me by Dr. Vander Veer, and used the following words: "Arthur McKee F——, born, 1891. Previous to his birth, a miscarriage and a still-birth. Mother had albuminuria every time [syphilis?]"

About a week ago I received from the father of the unfortunate baby a very indignant letter, dated June 9, 1894, in which he says: "I demand an explanation and insist upon a correction which shall appear in the next issue of the Medical Record."

Now, Mr. Editor, if after such a long time your space and your kindness permit you to publish all of this, I courteously offer the following "explanation" of my syphilis with interrogation mark in brackets, viz.: Successive miscarriages, to a certain extent also persistent albuminuria and excessive bone proliferation resulting from an irritative nutritive process, suggest the presence of syphilis in a late form. They do not prove it, unless there be corroboration by the history or the physical examination of the parents (mostly the father) or the wetnurse. The interrogation mark means: No certainty at all; at all events, justifiable doubt.

The "correction" is that "there was no such intimation whatever in Dr. Vander Veer's report;" that the father strenuously denies syphilis, and that, therefore, the cause of the poor baby's abnormal, both physical and mental, condition is not explained.

Very sincerely yours,
A. Jacobi, M.D.

PALATABLE AND DIGESTIBLE MILK.

To the Editor of the Medical Record.

Sir: A brief but suggestive editorial in your issue of July 28th, on the digestion of milk, prompts me to add one more to the devices by which the use of this most essential article of invalid diet may be made more agreeable to those who cannot, or think they cannot, take it "straight."

I have never seen it mentioned in any text-book, and it did not come to me from a professional source, but from a lady who had been for a long time the patient of the late Dr. Pease, of Syracuse. Whether it originated with him I cannot say, but perhaps some of your readers in Central New York, by whom he is doubtless as pleasantly remembered as by myself, can tell me. It is as follows:

A pint of milk is gently warmed. Into it is dropped, very slowly and with constant stirring, about twenty minims of the dilute hydrochloric acid of the United States Pharmacopœia. The milk should be stirred until it cools.

In this way a very fine flocculent coagulum is produced, floating in the whey, which is easily accessible to the digestive secretions, while the whole fluid has lost somewhat of the flat and cloying taste which makes it unacceptable to so many.

It will be noticed that milk prepared in this way differs from the various "wheys" in the highly important particular that the casein is retained and used, instead of being separated out as a distinct product, while it avoids the bitterness of pancreatized milk.

I have found it occasionally of great value when other preparations have been unacceptable either to the palate or the stomach. Robert T. Edes, M.D.

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 11, 1894.

	Cases.	Deaths.
Tuberculosis	70	88
Typhoid fever	37	6
Scarlet fever	23	6
Cerebro-spinal meningitis	0	6
Measles	16	0
Diphtheria	111	34
Small-pox	1	1

The True Physician longs for the time when in every fellow-practitioner he shall find a brother, a counsellor, a scholar, a gentleman.—W. J. Bell.

Lactate of Cocaine in Tubercular Cystitis.—Dr. Wittsack has found benefit from the instillation into the bladder, once or twice a week, of fifteen drops of a solution containing twelve grains of lactate of cocaine and one drachm of lactic acid in one drachm of water. Lactate of cocaine is a white substance the consistency of honey, readily soluble in water. It has not yet been obtained in a dry state.

Remarkable Fecundity.—An instance is related in the *Journal de Clinique et de Thérapeutique Infantiles* for May 10, 1894, of a woman, forty-nine years old, who had given birth to twenty five children. She had been married three times and had never had twins. Of the twenty-five children nineteen were boys, who had all died in childhood; the six girls had all lived, the youngest being five and the eldest twenty-eight years old. The woman had received a medal at the Sorbonne in recognition of her patriotic efforts to increase the population of France.

THE CURE OF CARCINOMA OF THE BREAST BY RADICAL OPERATION—OBSERVATIONS IN ONE HUNDRED AND EIGHTEEN CASES.[1]

BY WILLIAM T. BULL, M.D.,

PROFESSOR OF SURGERY, COLUMBIA COLLEGE, SURGEON TO THE NEW YORK HOSPITAL.

THE following series of cases, occurring between the years 1880–94, are offered as testimony to the value of the modern radical operation in cancer of the female breast. In every instance but one the diagnosis has been confirmed by microscopical examination, for which Dr. Frank Ferguson, pathologist to the New York Hospital, has been responsible in the majority. To the tracing of the cases through this number of years, and keeping the records up to date, January 1, 1894, Dr. Charles A. Powers, surgeon to St. Luke's and the New York Cancer Hospitals, has given much time and enthusiasm. He has been associated with me in the care of many of these patients during the past five years. To his efforts is due the circumstance that but 3 of the 118 cases have been lost sight of—a smaller percentage than is noted in any other record. Weir, for instance, traced but 60 of his 125 patients, Dennis was able to keep sight of but 33 of 71, and Curtis (MEDICAL RECORD, No. 24, 1894), in collecting the statistics of eight foreign clinics, gives final results in only 813 of a total of 1,213 cases.

In the matter of etiology, trauma, previous inflammation, heredity, and age, are found to play about the same rôle as is mentioned by other observers. There is no noteworthy difference from other statistics; and in these particulars, as well as in such details as the part of the breast affected, the relative frequency of disease of the right or left breast, this series gives no information of practical value. In passing I may, however, note the fact that of 13 cases in which cancer existed in the previous generation 11 were found among the recurrent and 2 among the cured cases; and furthermore, that I have taken no notice of the item of duration of the disease before operation, because the data in most instances are so untrustworthy. I have excluded all cases of secondary operations (about twenty in number) performed on patients with whom I had no previous experience, and have no records of patients in whom no operation was advised.

The practical value, then, of this record is in its showing as regards the question of cure, to which only a portion of the cases contribute, because not all operations have been complete or radical in character. As incomplete operations, which are ten in number, performed in the years 1880 to 1884, I include those in which the breast only was removed primarily; as complete, those in which the breast was excised together with a liberal amount of skin over it, the fascia of the pectoral muscle, and the glands of the axilla embedded in their fat. This thorough and admirably planned operation was first suggested by Moore, then advocated by Banks, in England, popularized by Volkmann in Germany, and warmly supported by Gross in this country; and it is now, I believe, generally adopted. It has been performed in 108 cases without reference to the condition of the glands as determined by examination prior to the operation.

The 10 incomplete operations were all followed by recovery; the 108 complete operations include 4 fatal results, the cause of death being in 2 cases erysipelas; in 1, chronic nephritis and pneumonia; in 1, acute sepsis and pneumonia. This is a mortality percentage of 3.6 per cent. Curtis, above quoted, finds a mortality-rate of "very nearly six per cent." in 1,213 cases, while Weir and Dennis have reported series of 125 and 33 cases, respectively, without death. For so small a mortality it seems hardly necessary to offer explanations, but it is worthy of note that all the patients were of the hospital class, that the two dying of erysipelas undoubtedly were infected in the hospital, and that the case of acute sepsis owed its existence to a streptococcus invasion from an undiscovered source. Curtis's statistics go back as far as 1870. The mortality of the later reporters is much less than that of the earlier, and in view of several series without any mortality, I think it may be averred that the complete operation is attended with but little more risk than the incomplete, and that in persons otherwise healthy and in operations unattended with accidents, it ought not to be greater than three or four per cent. This is a very slight risk for the patient affected with cancer to take, especially in view of the prospect of cure.

In order to determine the proportion of cures, we can utilize of the 108 only those cases which were operated on prior to 1891. Since that date there have been 30 operations. Deducting these and the three which have been lost sight of, I have 75 cases. Of these 75 cases 3 died from the operation; 50 died from recurrence or metastasis; 2 are still living with recurrence; 4 died of other diseases after having passed the "three-year limit" without manifestation of cancerous disease; 16 are alive and in good health on January 1, 1894.

This gives 20 cured cases out of a total of 75, or 26 6 per cent. This is a higher proportion of cures than has been previously reported. Curtis gives 20.7 as the percentage of cures in the 1,213 cases he collected. Weir "nearly twenty," and Dennis twenty-five per cent. The value of my percentage is increased, I think, by the fact already mentioned, that but 3 cases of 108 have been lost sight of.

Regarding these 20 cured cases more in detail, let me say of the 4 who died of other diseases, after passing the "three-year limit," that

One died at the end of 5 years, of pneumonia.
One died at the end of 3½ years, of chronic bronchitis and emphysema.
One died at the end of 3½ years, of acute rheumatism.
One died at the end of 3 years, of chronic nephritis.

The 16 cases still alive and free from recurrence have lived on an average six years and a few days since the operation. To be more explicit:

Two are living and well 3 years and 9 months after operation.
Four are living between 4 and 5 years after operation.
Three are living between 5 and 6 years after operation.
One is living between 6 and 7 years after operation.
Three are living between 7 and 8 years after operation.
One is living between 8 and 9 years after operation.
One is living between 9 and 10 years after operation.
One is living 10 years after operation.

These cured cases are all the more significant because of the extent of time they have remained cured, the average, six years, being twice as long as the "three year limit." Only 2 have undergone secondary operations. Of the

[1] Read at a meeting of the Surgical Section of the Massachusetts Medical Society, June 12, 1894.

4 who died free, 1 had a recurrent nodule removed at the end of four months, and died of rheumatism over three years later. Of the 16 still living, one had three nodules removed at periods of six months, seven months, and eighteen months after the primary operation, and is living five and one half years since the last operation.

In computing the percentage of cases I have included in the total of seventy-five, the three patients dying from the operation. This class has been deducted by some reporters. I have excluded from the "cured" list one case which died of cancer of the œsophagus nine years after the operation on the breast and axilla, having been free meanwhile from recurrence—a case which might be fairly regarded as an instance of fresh infection, or the development of a growth entirely independent of the original disease. Poulsen[1] has reported an instance of cancer of the pylorus developing five years after an operation on the breast, which is capable of a similar explanation. I have accepted the "three-year limit" as evidence of cure in order to make my statistics to conform to those of others. It seems to be true, in the majority of cases, that recurrence takes place in loco, and metastatic deposits occur within this time, though instances of a later development of both features are not rare. Curtis, from various sources, records thirty-four recurrences after three years and up to the seventh year. Weir has seen one at sixteen, and one at twenty years. I am not able to give the precise data of recurrence in many cases, but can say that the average duration of life in cases dying of recurrence or metastasis was less than three years, and that I have observed no instances of reappearance of the disease after three years. A four-year limit would be undoubtedly more accurate. Judged by this standard, my list of cures would be reduced by only 5 cases, making 15 cures in 75 cases, or a percentage of twenty, the same that Curtis's 1,213 cases give with the year limit.

The patients operated on since 1891, not available for the question of cure, are 30 in number, of whom 10, or thirty-three and one third per cent., are without recurrence and with prospect of cure, though an average of but fifteen months has elapsed since their operations. Two died within eighteen months from the time of operation, free from cancerous disease; 1 died from the operation, which is already counted in the list of deaths; 11 have died of cancer already, and 6 are living with recurrent disease.

The record of the incomplete operations emphasizes the advantage of the complete or radical method of treatment. Of 10 patients in whom only the breast was removed, all died of cancer at the end of an average period of thirty-four and one-half months, 3 having undergone several secondary operations. It is my conviction that, except as a palliative method, this form of operation should no longer be countenanced. It is unquestionably attended with less risk, as numerous statistics have shown, but our knowledge of the course of the cancerous diseases, and the absence of statistical facts to support it, demonstrate that it is an utterly inadequate method.

In every case of cancer, whether the glands of the axilla be felt to be enlarged or not, the complete operation should be done. It removes not only the diseased area, but the parts more likely to be affected by recurrence, the skin and pectoral fascia, which have been shown by Heidenhain to be often the seat of deposits which may escape the naked eye. It clears out the axilla, the next resting-place of the neoplasm, whose glands may be enlarged from disease without their presence being discovered by external examination. Only in abnormally thin subjects can one be reasonably sure of the condition of the glands, as many surgeons have testified. It should do more than this, and that is, remove the parts between the axilla and the breast, the region through which the lymphatics pass. In my operations, as the accompanying cuts will show, I have been in the habit of removing the parts in one solid mass from the inner periphery of the breast to the apex of the axilla; and this detail, which is not generally insisted on, I regard as of great importance.

[1] Arch. für klin. Chir., 43, p. 592.

Without quoting other statistics, it may be safely stated that the complete operation has been, since its introduction, attended with a diminishing mortality and an increasing percentage of cures. It has unquestionably been done in many cases in which it could promise little on account of the extent of the disease. One cannot avoid this conviction in reading the histories of individual patients, and I know that, in many hospital and some private patients, I have performed operations under circumstances which a maturer judgment and larger experience would now regard as contra-indications to the operation. If we could expunge from all our lists the number of these advanced cases, the showing would be a very much more encouraging one. My notes are not

Fig. 1.—Cancer of the Nipple, Breast, and Axillary Glands, following Ulceration of the Nipple for Eleven Months.

Fig. 2.—Cancer of Breast and Axilla, to Show Amount of Tissue Removed.

sufficiently full in the matter of extent of the disease to enable one to make any such distinction. Such points as adhesion to the wall of the chest, involvement of the pectoral muscle, fusion of the cancerous glands, and adhesion to the axillary vessels are rarely mentioned, though all or some of these conditions have been met with in a considerable number of cases. But in regard to involvement of the axillary glands I can give some data.

Of the 20 cured cases the breast alone was affected in 12, while in 8 both glands and breast were involved. Of 55 cases dying (3) of the operation or recurrence (50), or living with recurrence (2), the glands were involved as well as the breast in 38, while in 10 the glands were free from disease. In 7 the condition is not stated. In other words, of the cured cases forty per cent. had both breast and axilla affected. It should be stated that the evidence of involvement of the glands in most cases was determined by microscopic examination, and that in

many the deposits in this region were detected only after the axillary fat was cut into.

The complete operation, then, is capable of effecting a cure even when the glands are involved, and that in a considerable proportion of cases; and if we make a sharp distinction between the cases according to the condition of the glands, we shall get the following more encouraging picture of the 75 cases:

This condition was not noted in	17
Breast alone affected in	22
Breast and glands affected in	46
Total	75

Of 22 cases in which the breast alone was diseased, 12, or about fifty-four per cent., were cured, 10, or forty-five per cent., died of recurrence. Of 46 cases in which both breast and glands were involved, 8, or seventeen per cent., were cured, and 38, or eighty-two per cent., died of operation, or a recurrence, or are living with recurrence. This showing would support the statement that in at least one-half the cases of cancer limited to the breast alone the complete method may be expected to effect a cure. The deaths, it is to be noted, are all among the cases where both glands and breast are involved. Delaying the operative treatment, then, not only increases the death-rate but diminishes the prospect of cure. Patients ought to be subjected to the complete operation in the earliest stages of the disease. There is no longer any excuse for delay on the part of physicians, on the ground that more time is needed to make a diagnosis, and the laity, if made aware of the possibilities of cure, will promptly overcome the dread of operative treatment, which is another reason for delay. Irregular practitioners furnish the public with the strongest representations, or misrepresentations, of the success of other methods which we know to be of less value than the operative ones. Why should not the regular profession, through its public representatives—the Boards of Health—be equally active in informing the people of the danger of delay, and the promise of cure by early and radical treatment?

In a condition, the successful treatment of which depends absolutely on its promptness, exactness in diagnosis should play a secondary rôle. A lump in the breast is never a "nothing," as it seems occasionally to be termed by physicians who see it first. It is either an inflammatory deposit, or a solid or cystic tumor. Between the two latter conditions it is often impossible to distinguish in large and even small breasts. But the hypodermic syringe and needle, which should be used in all doubtful cases, clears up this point at once. With its use I have demonstrated the harmlessness of cases which have been viewed with suspicion or pronounced malignant by others, and in passing may note that I have encountered thirty cases of simple cysts of the mamma in the past ten years, probably about ten per cent. of all the cases seen. If a tumor be thus proven to be solid, exploratory incision should be made the diagnostic test when its features are doubtful. Naked-eye inspection will usually suffice, though the freezing microtome and the nitric-acid test of Stiles, or the "punch" devised by Mixter are unobjectionable. They can be employed when the incision is not allowed. There is no reasonable objection to the incision. A benign growth demands operation almost as urgently as a malignant one, for we have ample testimony of the degeneration of these tumors into malignant ones at or after the menopause. Inflammatory deposits can suffer no harm from incision or renewal. They are liable to be the precursors of cancerous disease, and can be looked upon as safe, and entitled to be unmolested, only when they are disappearing spontaneously after a recent acute mastitis. I have two cases bearing on the degeneration of benign tumors which are worth recording. The first, a woman, aged forty-five, noticed a rapid growth of a tumor which had been quiescent in one breast for sixteen years. At the end of one year the whole breast was transformed into a typical carcinoma, which was removed without the glands. Two secondary operations were done, followed by local recurrence, and she died, at the end of five years from the beginning of the disease, with cancer of the liver. The second, aged seventy-five, carried for eighteen years a small painless tumor, which in one year involved the greater part of the breast and the axillary glands. One complete and one secondary operation were followed by death from cancer of the lungs and pleura after twenty months.

A condition of chronic eczema of the nipple (or Paget's disease) giving rise to cancer, I have met with in four cases, which are noticeable because the duration of the ulceration did not exceed one year, being four months in one, eleven months in a second, and about a year in the third or fourth. In two the glands as well as the breast tumor underlying the ulcer were cancerous. The ages were forty-eight, sixty, fifty, and forty years. One patient, operated on a year ago, is still alive and free. Two died of recurrence within two and a half years. One lived eighteen months free from trouble, to die of pneumonia. One patient declined any investigation of the axilla, and was obliged to undergo a secondary operation eight months later, which revealed glands which must have been diseased at the time of the primary and incomplete operation. The importance of these cases should not be overlooked. Although it has been noted that these eczematous conditions often go seven and even ten years before the development of cancer, it is proper to regard them with suspicion, and desirable to treat them promptly by complete operation so soon as milder measures fail.

In one of the above cases, where an ulcer had existed—refusing to remain healed under the application of ointments for a period of eleven months—I had a wedge of the base of the ulcer removed for examination by the pathologist, who pronounced it only "chronic inflammation." In view of the duration of the ulceration and its well-known tendencies, I urged exploratory incision. A part of the ulcer deeper than the mass removed looked surely cancerous. The whole breast was removed, and the axilla invaded. Subsequent investigation showed the breast to be cancerous in the neighborhood of the ulcer, and the glands not to be affected. These might be considered cases of primary epithelioma of the nipple, but the fact remains the same, that a persistent ulceration of the nipple often leads to cancer, and must not be neglected.

It has been generally claimed that the complete and even the incomplete operation, when it fails to cure, prolongs life and makes its ending less distressing. I have not the data at hand to give figures bearing on these points, because the duration of the disease, as proven by patients, is so indefinite; but I can safely say that, judging by the results so far as the duration of life is concerned, in those which have undergone secondary operations, and those which have not, the operated cases have the advantage. For instance, of ten incomplete operations all died of cancer at the end of an average period of $34\frac{1}{2}$ months; seven of these, without secondary operation, lived on an average of $23\frac{6}{7}$ months; three, who had secondary operation, lived an average of $58\frac{1}{3}$ months after the first operation. Of sixty patients with complete operation I note forty-seven who died without any but the first operative interference, $20\frac{34}{100}$ months; while thirteen who had one or several operations subsequent to the first, died 30 months afterward. But one single case is worthy of mention. A woman, aged fifty, underwent the complete operation for a tumor of breast alone of two years' duration. She died of cancer of liver, lungs, and pleura, at the end of eight years and eight months after the operation, ten years and over from the outset of the disease. In this interval five operations were performed, including one on the opposite breast.

Operations, in my opinion, do prolong life, and I am quite sure they have a further advantage in regulating the course of the disease, so as to make it more bearable.

In a certain number of cases there is no external outbreak, and the patient dies of internal deposits without knowing the nature of her malady. The annoyance of a foul and bleeding ulcer is avoided, with the pain that comes from involvement of the walls of the chest. Furthermore, the clean removal of the axilla diminishes the chance of interference with the venous circulation and the occasion of that distressing feature—œdema of the entire arm.

These facts encourage me to advise secondary operations when the growths are small and freely movable. Several such operations may be required without materially diminishing the prospect of final cure; but in general I have little faith in the value of secondary operations, except as palliative measures. I believe it is an excellent measure in dealing with the first occurrence to give an anæsthetic and inspect thoroughly the whole line of the cicatrix, rather than to trust to the removal of the growth with the use of cocaine. This "revision of the scar," as I have termed it, done at the moment of the first recurrence, has enabled me to find and remove nodules that were not felt on palpation. The cocaine operations, of which I have done a number, have seemed to me exceedingly unsatisfactory.

In the axilla the removal of recurrent nodules or glands is often a matter of difficulty, owing to the presence of cicatricial tissue and the likelihood of finding deeper masses adherent to the axillary vein. Excision of a portion of the vein is required in the latter event, a procedure which I have never known to give rise to unpleasant results, but which may in its performance offer an opportunity of wounding the vein several times unawares, with serious hemorrhage. In general, operations for recurrent masses which are adherent either in the axillary or breast part of the scar, I have found to be of no advantage whatsoever.

The operation itself needs no description in detail, but there are several points which are worthy of emphasis. The skin incision should in general conform to the oval type—a widely open oval—and extend from a point near the sternum to one overlying the axillary vessels. Its long axis may be at right angles to the direction of the pectoral fibres, with a second cut in the axillary region, if the tumor be most conspicuous at the upper and inner, or outer and lower, periphery. Its outline is of little consequence. Its distance from the neoplasm is of the greatest importance. When the growth is in the breast I have usually placed the incision at least one inch from the borders of the gland, where it is peripherally situated two inches from the edge on the side affected. The cut must be made without reference to subsequent approximation of the edges, though much tissue can be advantageously saved in the axillary part of the incision, and in the majority of my cases a primary union has been possible. After separating the mamma itself it is allowed to hang down, still in connection with the axillary part, till the parts between the breast and axilla and the contents of the latter have been separated. There is little danger of wounding the axillary vessels if the fascia over the vein is first clearly laid bare and the mass of vessels and nerves gently pushed away from the fatty contents, the vessels crossing the space being clamped before they are cut. The subscapular nerves must be avoided, but the intercosto-humeral branches must not be cut. After the axillary space has been freed of its contents, search must be made at the very apex, and in the region between the two pectoral muscles, where outlying glands are occasionally found. In closing the wound I have given up all sorts of relaxation sutures and come to rely on fine catgut. The edges are brought only loosely together without any strain, but carefully approximated to the deeper parts with compresses supported by adhesive straps. The axillary space must be obliterated by an additional wad of gauze. If open wounds are left, it is better, in my opinion, to practise skin-grafting after granulation has occurred. The operations have naturally, in the course of these years, run through the various modifications of antiseptic dressings. The most recent cases show the most satisfactory results, and these have been done on aseptic principles, with sterilized materials and without irrigation or drainage. Complete primary union without complication has been obtained in fully two-thirds of the cases, and, where it has failed, there has been no serious sequelæ nor prolonged suppuration. In two instances erysipelas was fatal. Operations done in private houses have produced uniformly good results as regards wound healing. There have been no serious after effects of these operations. Some patients are much annoyed by a hyperæsthesia of the skin on the inner side of the arm, which gives place to numbness which gradually disappears. This phenomenon has been such a frequent source of complaint when the dressings are removed that I usually lead patients to expect it, and promise that it will disappear.

The movements of the arm and shoulder joint have become ultimately perfect in all cases. I usually encourage motions from the elbow on the fifth day, and those of the shoulder after the tenth day, and on the average the slight stiffness yields to natural exercise within three or four weeks.

In closing, let me say that I have made no distinction in this series between the different varieties of carcinoma, because of the difficulty of assigning many cases to an individual class. But I should state that I have uniformly advised against operation in the variety known as "atrophying scirrhus," occurring in old people, and in the rapidly growing voluminous tumors occurring between thirty five and forty-five, and described as encephaloid or medullary carcinoma.

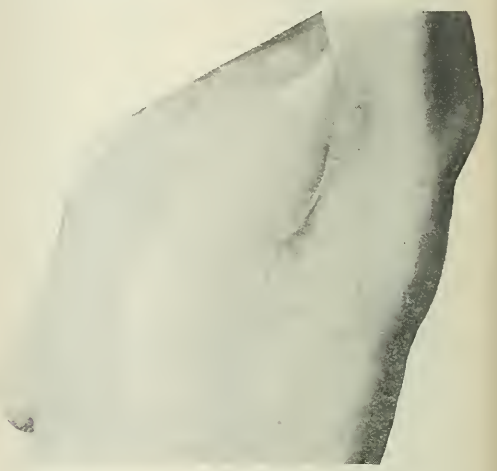

FIG. 3.—Cicatrix, with Free Mobility of Arm, Four Years after Operation.

I thank the Massachusetts Medical Society and yourself, Mr. Chairman, for the privilege of bringing before you these results of treatment of this most important surgical disease; and I hope that your experience may be in line with my own and will serve to strengthen our convictions, that the modern radical or complete operation has already cured from twenty to twenty-five per cent. of all cases of cancer of the breast; that it may be expected to cure at least one-half the cases if applied before the axilla is invaded; and that it is likely to have an even better showing if the patients can be brought to treatment earlier than they manage at present. This can be effected by less attention to accurate diagnosis, and by giving up the habit of waiting to see how the tumor will develop, and by relying on needle exploration and incision. The incomplete operation should be abandoned, except as a preventive measure, or for the relief of local symptoms. Benign neoplasm and inflammatory deposits

should be removed, and persistent ulceration of the nipple treated as cancer. Secondary operations are of value only when the nodules are small and free from adhesions, and the "revision of the scar" should be performed in the event of the first recurrence after complete operation. The risk of the complete operation is slight, and it is followed by no undesirable after effects.

35 West Thirty-fifth Street.

ON THE NEW RELATIONS OF PATHOLOGY AND PRACTICAL MEDICINE AS BEARING UPON THE PATHOLOGICAL DEPARTMENTS OF OUR HOSPITALS.

By JOHN SLADE ELY, M.D.,

PROFESSOR OF PATHOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY; ASSISTANT IN PATHOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; PATHOLOGIST TO BELLEVUE HOSPITAL.

In the progress of every science a period of fact accumulation must precede the more strikingly epoch making one of generalization. Until generalization commences but little practical application of the facts accumulated is possible. Pathology affords many examples of the truth of this great principle of all inductive science. Its clear perception stimulated Morgagni and his followers to collect the carefully corroborated facts which a century later suggested the generalizations of the cellular pathology of Virchow; and, similarly, the facts accumulated by Pasteur in the study of fermentation and putrefaction, made possible the even greater generalization of the causative relationship of micro organisms to disease. A glance at the influence of these generalizations upon the study of disease and upon the relation of the pathologist to the clinician is most suggestive.

The enunciation of the fundamental law of the cellular pathology, *omnis cellula e cellula*, drew attention to the cell as the ultimate living factor in the production of the lesions of disease. The cell and the tissues to which it gave rise thenceforth became the prime objects of study to the pathologist. This resulted in the accumulation of a vast fund of knowledge of the morbid anatomy of disease. The great usefulness of this study to practical medicine was evident in the greater accuracy of diagnosis, and, secondarily, in the juster appreciation of the limitations of medication. So long as it was the dominant force in pathology the careful autopsy and subsequent examination of the tissues met all the absolute requirements. They acted as a check upon diagnosis, showing the clinician his error when it existed, and so helping him in subsequent cases of the same nature to a more correct interpretation of the symptoms. From the very nature of the case the work of the pathologist was largely post mortem. He was often deplorably ignorant of the pathology of minor ailments not usually followed by death, he had but a secondary interest in symptomatology (in reality an important part of pathology in its broader sense), and he was rarely called upon to assist the clinician at the bedside The position occupied by pathology during this time was, then, essentially that of a pure science; it had but a limited practical application.

But, with the development of the idea of the etiological relationship of micro-organisms to disease a new epoch has opened. We have been taught that many diseases are the result of the entrance into the body and growth there of noxious living organisms; that the changes which the study of morbid anatomy showed to be characteristic of these diseases, are the result of the action of these organisms upon the tissues of the body; that this action is produced by poisonous substances elaborated by the micro organisms, some of these toxines expending their energies upon the tissues in the immediate neighborhood of the growing germs, while others are diffused throughout the body, giving rise to fever, prostration, etc., symptoms more or less common to all diseases of infectious origin.

By these discoveries new interest is awakened in the alluring field of preventive medicine, for it has been established that without the agency of the specific microorganism of an infectious disease, that disease can never originate. Prevent its entrance into the body, and the disease is prevented. Thus, the interest attaching to the determination of every detail of the life history of the microbes of disease becomes immense, many new problems at once suggesting themselves. What is the path of entrance of the specific organism into the body; in the air inspired, in the food, or through the skin? Through what channel does it leave the body of the patient? What is the manner of its dissemination, its resistance to drying, sunlight, heat, etc., its habitat during the interval of its transmission from one person to another? Without a thorough knowledge of all these points it may be impossible to institute an efficient plan of prevention. And, furthermore, we inquire whether, in certain diseases in which prevention of the entrance of the infectious material into the body may be impracticable, it may not be possible nevertheless to induce a condition of immunity to its action, in this way accomplishing the same ultimate result? Thus the influences inducing a predisposition to, and those inducing an immunity from, the action of the contagium of infectious diseases must receive most careful investigation.

It must be evident, then, that the determination of the causal relationship of micro organisms to disease has revolutionized the whole science of pathology, very greatly widening its scope and increasing its usefulness to the clinician tenfold. The student of pathology must in future acquaint himself with subjects which until recently were supposed to have little, if any, bearing upon disease. It is no longer sufficient for him to confine himself to the study of morbid anatomy, but he must now also search for the living causes of disease, he must study their peculiarities of structure and growth, their mode of action upon the body, the toxines which they elaborate, their paths of entrance to and egress from the body, and the various problems of their destruction and the prevention of their ravages. In his search for the cause of a disease he need not wait until death has brought his victim to the autopsy-table, for experiment has shown that often during life the germs of a disease are present in the blood and in the various excreta of the body, as are also the chemical poisons which they produce. Thus, early in the course of the disease the aid of the pathologist is sought in diagnosis through examination of the sputum, vomitus, blood, urine, fæces, and various inflammatory products. Upon the result of his examination the subsequent treatment of the case will often largely depend.

But, besides the changes in pathology wrought by the study of the causation of disease, the past ten years have added greatly to our understanding of pathological physiology, if the expression may be allowed, meaning thereby the perversions of function which are the result of disease.

Those evidences of disordered function accessible by the ordinary means of observation, and spoken of as the symptoms of disease, while really a part of pathology in its broader sense, have come very properly to belong to the domain of the clinician, and with them the pathologist has ordinarily but little to do. But a multitude of evidences of disordered function are inaccessible to ordinary observation, and for their detection the services of the pathologist are required. Foremost among these at the present time are the changes in the chemistry of the body which occur as a part of disease, and the immense importance of the study of these changes may be inferred from the fact that chemical change has been shown to be a necessary part of all vital process. Accordingly, with the aid of the facts accumulated by the study of physiological chemistry, we are beginning to build up a pathological chemistry which promises to be of great practical value. During life the study of the chemical changes indicative of disease is of necessity restricted to the examination of the various secretions and

excretions of the body; but as the result of the careful study which they have received we shall soon be able to infer with much accuracy, from changes in their chemical composition in disease, as to the nature of the processes upon which their abnormalities depend. Already, examinations of stomach contents, of urine, of fæces, of exudates and transudates, and of the blood have become an important part of the daily routine of the pathologist. He must be acquainted with the best tests for hydrochloric acid, for pepsin, and for the abnormal products of digestion in the stomach; he must be able to determine the quantity of albumin, sugar, urea, uric acid, sulphates, indican, etc., in the urine; he must know how to detect the results of imperfect intestinal digestion in the fæces; he must be familiar with the changes in the composition of the blood dependent upon diseases of the various organs of the body. But these are only a few of the problems suggested by the development of pathological chemistry. Their immense importance to clinical medicine cannot but be apparent.

Closely in touch with the new duties imposed upon the pathologist by the study of the chemistry of disease, are others which have been suggested by the results of the investigation of the various problems of immunity. The self-limited course of the infectious diseases, and the protection afforded by one attack of many of them against subsequent attacks of the same disease, have long been recognized. The recent study of immunity explains this by the theory that, hand in hand with the production of the toxines of these diseases, there are produced (by the cells of the body, presumably) certain antagonistic substances which neutralize the toxic principles and thus prevent their action upon the body. These antagonistic substances are called "antitoxines," and the extent of their production is supposed to measure the degree of immunity produced. It has been found that these antitoxines are present in the blood of animals rendered immune by artificial means, that the blood of an animal so immunized possesses the power, when introduced into the body of other animals, of conveying its immunity to them, and, more important than all, of ameliorating the symptoms produced by a previous inoculation with the infectious material. These facts have been shown to apply to man as well as to the lower animals, and thereby has been suggested a plan of treatment of infectious disease by means of the blood serum of immune animals, which appears most promising from the reports thus far published. It is to the pathologist that the clinician must look for the induction of immunity in animals and the preparation of the blood-serum necessary for this treatment.

Now, it must be evident that the advances in pathology which we have sketched demand on the part of the pathologist a special training for his work, and the devotion to it of an amount of time and labor quite beyond the possibilities of the clinician. He must now have a thorough acquaintance with bacteriology, animal chemtry, and toxicology in addition to his knowledge of pathological anatomy. He must have trained powers of observation and of experimental research, and he must have at his disposal laboratories equipped with every appliance necessary for the conduct of his investigations.

And this leads us to speak of the necessity of much further development than has yet occurred in the way of providing pathological laboratories in connection with our hospitals. We are justly proud of the flourishing laboratories of pathology which have grown up in connection with many of the medical colleges of this country, and of the careful investigations of the problems of disease which are being carried on in them. But by the development of such a wide field of practical applications pathology has, of necessity, become more or less divided into two distinct though closely associated departments, that of the pure science of pathology occupied with the theoretical solution of all the problems of disease, and that of the applied science of pathology occupied with the application of all the principles of the science to the practical uses of the clinician. Though fulfilling all the requirements of the first, the laboratories of our medical schools in only a secondary way meet the demands of the second. Connected with educational institutions, they are conducted primarily for educational purposes; the time of those connected with them has many demands upon it for routine work in connection with large classes of students; and unless at great expense of time, the pathologist is never brought into contact with the patient, because of his distance from the hospital. Thus, the direct usefulness of the pathologist to the clinician can be but slight.

It is evident, then, that the true ground for the development of pathology as applied to clinical medicine is the hospital and its thoroughly equipped laboratories, and we would insist again that without these, the clinician must forego to a very considerable extent the great assistance in his work afforded by the pathologist. It is surely no unreasonable demand on the part of the patient, that his physician should be in possession of every aid afforded by modern science in the treatment of his case.

What, then, is the equipment which a hospital should have in order to be abreast of the times in so far as pathology is concerned? Besides the thoroughly equipped autopsy-room, with its adjoining refrigerators for the storage of bodies, there should be laboratories devoted to histology, bacteriology, and chemistry. These should be well lighted and well ventilated, and should be sufficiently large to afford abundant working space, and to contain all the apparatus required by the most recent advances in these several branches of science, in so far as they bear upon pathology. The histological laboratory should be provided with a good outfit of microscopes, microtomes, and everything necessary for the minutest study of the structural changes of the tissues in disease. It should have the best light obtainable, and should afford ample shelf room for the storage of the pathological material which must be accumulated for study. The bacteriological laboratory should afford every facility for the cultivation and study of the micro-organisms of disease. It should be removed as far as possible from the possibility of contamination by dust or other disturbing influences, and for use in connection with it there should be a room fitted up for the accommodation and observation of animals used for the experimental determination of the pathogenic action of the bacteria. The chemical laboratory should contain a complete outfit of apparatus for the examination of the various secretions and excretions of the body, for the separation and study of the toxines of bacteria, and for the preparation of materials for preventive inoculation and for the treatment of disease by means of the blood-serum of immune animals.

All this involves a considerable outlay of space and money on the part of the hospital, but these are more than counterbalanced by the many advantages to its patients to be derived from such an equipment. The space and light may best be obtained in a separate building especially devoted to the pathological department; the annual expense incident to the conduct of such a department, after the first outlay for building and equipment, would be relatively small.

And, finally, the hospital should be able to command the services of a man as director of such a department, whose time and energies are entirely devoted to the scientific development of applied pathology. It is no longer possible for pathology and practical medicine to be carried on successfully together, and, since in giving his services to the hospital the pathologist must be debarred from other means of support, he should receive a salary sufficient for his needs and sufficient to put men of ability at the command of the hospital.[1] The proper conduction, then, of a pathological department such as we have endeavored to sketch, demands the payment of

[1] It would seem that a fair criterion of the amount necessary for this purpose might be found in the salaries paid by our universities to their professors of pure science.

good salaries to its director and his assistants, and the affording them every facility for scientific investigation.

The educational and scientific power of a hospital equipped as has been suggested is simply inestimable. Already the Institut für Infectionskrankheiten in Berlin has made its influence felt the world over, and it is to be hoped that America, by following the lead thus shown, may come to occupy the same advanced position in the onward march of scientific medicine which it has long held in many of the more purely practical branches of our science.

THE SHADY SIDE OF THE SURGICAL TREATMENT OF TRACHOMA.[1]

By H. GIFFORD, M.D.,

OMAHA, NEB.

THE surgical treatment of trachoma, which dates back at least to the days of ancient Greece, has had, as you all know, a most enthusiastic revival during the past few years; and granulated lids are being treated with all sorts of inventions and adaptations, from roller forceps to rasps, tooth-brushes, and pumice stone. It is not my intention to discuss the merits of these various methods; any one of them, properly used, in connection with other treatment, gives better results than the treatment with local applications of any kinds of medicines, alone; but the praise of them has been so indiscriminate, and the disadvantages and dangers of the treatment have been so little dwelt upon, that it is high time for the other side of the case to receive more attention. That it may be clear that I have no unfounded prejudice against the surgical treatment of trachoma, let me state that I have been chloroforming my trachoma patients and subjecting their lids to the most vigorous surgical measures, squeezing, cutting, burning, and scraping, according to the case, for nearly seven years; several years longer than nearly all the writers from whom so much has been heard on the subject. Moreover, as nearly one-fourth of my patients, both private and clinical, come to me for trachoma and its effects, my experience cannot be said to be limited. Furthermore, I have no idea of belittling the immense advantage which surgical measures give us in treating the disease. I should not think of trying to do without them. I merely wish to point out that the brilliant results claimed by so many writers are not, as a rule, to be expected, and that disastrous results may follow their use in some, if not all, classes of cases. First, as to the brilliancy of the results. Many writers claim to cure the great majority of their cases in from four to six weeks; these claims, I feel sure, are due to too brief an observation of the cases. The patients feel well and look comparatively well, but if they are kept track of, relapsing will be found to be the rule; and in many cases I have gained the impression that corneal complications are more apt to occur in the relapses following so called cures with surgical means, than when medical applications alone have been employed. Where the diseased tissue is so localized that it can easily be excised, squeezed, or scraped out, a cure can sometimes be effected with one operation; but, generally, after all the surgical treatment that is advisable in the course of a month or six weeks, I find it desirable to have patients continue applications of sulphate of copper for many months, returning occasionally for such further surgical interference as may be required.

With regard to the dangers of surgical treatment, the bad results which I have observed or known to follow it are, first, suppression of tear-secretion, with resulting xerophthalmia; second, ulceration of the cornea, with partial or complete loss of sight. Respecting the first of these, I have seen several cases where, after excision or squeezing out, of the upper retro tarsal folds, the secretion of tears has been decidedly reduced. Most of these patients experienced no serious inconvenience from this reduction. In one old case, however, where the trachoma in one eye was reduced to a few gelatinous bunches in the upper fornix, near the outer canthus, these were squeezed out, and in spite of every precaution to prevent adhesions, the secretion of tears was almost entirely abolished, so that the patient was obliged constantly to use vaseline in the eye to keep it comfortable. It is quite possible that this eye would have become xerophthalmic, no matter what treatment might have been used, but it was a very unpleasant experience to have an eye which I was expecting to make useful and comfortable, made entirely incurable within a few days, as the result of my treatment.

Slight corneal erosions I have seen develop in several cases immediately after surgical treatment of the lids, but as in most of these cocaine had been used freely, it is questionable whether the majority of them should not be laid at the door of the latter. Really dangerous corneal trouble from surgical trachoma-treatment, I have observed only from the aggravation, by the operation, of pre-existing corneal affections. Most writers speak of the rapidity with which corneal complications heal after the lids have been treated surgically, and in the great majority of cases this has been my experience also. Trachomatous pannus, in particular, clears up with great rapidity after proper surgical measures. On the other hand, I believe that non-vascular ulcerations, whether superficial or deep, should be considered positive contraindications to any extensive surgical interference with the lids. Not that they too will not, as a rule, be helped by such interference; for they generally heal promptly; but in rare cases, without our being able to foresee the dangers, they become so rapidly worse after operations for trachoma that the sight is severely injured, or entirely destroyed, before they can be checked. I have had two experiences of this kind and know of three others. The first of my cases was that of a young man with moderate trachoma and nearly clear corneæ, there being only a slight superficial ulceration in the upper half of the left cornea. I excised the upper retro-tarsal folds, put in two stitches on each side, and applied a moist sublimate dressing. On the second day he complained of severe pain in the left eye, and on examining it I found a nearly central ulceration, about one eighth inch in diameter. This healed slowly, when the stitches were removed and hot applications used, leaving considerable permanent impairment of vision. The stitches may have been the cause of the bad result in this case, and since then I have not used them after excising the folds.

Another case was that of a woman, aged forty-two, whose right eye had been lost some years before. The left lids had some trachomatous infiltration; the upper three fifths of the cornea was in a condition of pannus; the lower two-fifths being clear except for a small superficial ulceration near the lower border. Under chloroform, the trachomatous parts of the lids were squeezed out with ring forceps, after which the conjunctival sac was washed out every two hours with a boracic-acid solution. The operation did not involve nearly as much rough treatment as is often required, and the reaction on the part of the lids was no greater than common, but the ulcer became rapidly worse and completely circumscribed the clear portion of the cornea, before the most vigorous measures, including a broad Saemisch cut, succeeded in checking it. As it was, all that portion of the cornea which had been clear became permanently dimmed, and until the vessels began to clear off in the upper part of the cornea, I had a practically blind woman on my hands. I am convinced that if the pannus had not existed on the upper part of the cornea, this, too, would have been involved in the ulceration; but the latter stopped sharply at the border of the pannus, and when the vascularization cleared up, as it soon did, useful vision was restored.

In another case which I have seen, the trachomatous lids of a man aged thirty-three were squeezed out with ring forceps by one of the most competent and skilful oculists of the West, who has had an unusually large ex-

[1] Read before the Omaha Medical Society, January 10, 1894.

perience in the surgical treatment of these cases. Before the operation, the man could see well with both eyes, though an ulcer existed in the upper part of the right cornea. After the operation, this ulcer spread so fast that the man never saw again with the eye; almost the entire cornea sloughed, and when I saw him, some months afterward, the eye was sightless and had to be eviscerated, on account of infection of the interior through the scar.

Another still sadder case, which I have recently seen was that of a middle aged woman from western Iowa, who had had trachoma for years. Finally her physician announced that he had a new and sure cure for her sore eyes, and proceeded to scarify her lids and apply what was probably sublimate 1 to 1,000. From her history, she probably had some moderate corneal complication at the time of the operation; at any rate, she never saw again. Both corneæ ulcerated and sloughed, and when I saw her, five months later, both eyes were hopelessly blind. How many similar cases are occurring all over the country, it is hard to say; such occurrences are not the things that one commonly likes to describe from his own practice, but I have recently noted a case[1] from the practice of Abadie, the ardent Parisian advocate of the tooth brush method of treating trachoma, in which a woman's conjunctiva (not trachomatous but with a conjunctivitis of uncertain origin) was brushed vigorously and the galvano-cautery applied to a granulation tumor of the conjunctiva; whereupon, a slight corneal infiltration which existed at the time of the operation promptly got so much worse that the whole surface of the cornea was reduced to a purulent pulp. The patient is said to have eventually obtained some useful vision of the eye, but for this she certainly had to thank her good fortune and not her surgical treatment. [Since this paper was read, I have learned of a case not included in the above, in which the scarification of the lids cost the patient his eye.]

These cases make it plain, I think, that surgical measures have not simplified the treatment of trachoma; on the contrary, they have made it altogether more imperative that he who uses them should be able to examine the eye with the greatest care and discrimination; and should be prepared, if unusual emergencies arise, to treat them promptly and vigorously. Without these qualifications, the physician had far better stick to the old bluestone and nitrate of silver treatment; for with these remedies the disease can always be improved or held in check, and in many cases cured; whereas, if he uses surgical measures at all freely, while he may, as a rule, obtain more brilliant results, he is liable, at any time, to ruin an eye which otherwise would never be lost.

Medical Practice in Sweden.—In Sweden ten years of study is incumbent on every medical student. They are so particular in that enlightened country to have their medical men thoroughly equipped and "ethically developed" that the practice of homœopathy is forbidden, and every globule of homœopathic medicine introduced into the country has to be smuggled in.—*New York Medical Times.*

Fruit Eating to Cure All Ills.—A new society of cranks has been started by a former lieutenant in the German Army. His name is Boeter. He is the leader of a new "ism," and as such sailed recently from San Francisco to Honolulu. The "Fruitarians" is the name of the new society he represents, and their belief—or rather notion—is, that modern civilization is full of vanities and strange notions, and greatly needs reforming. The members eat nothing but ripe fruit, eschew cooked food of any kind, and drink only water. They are to live in huts, bare of the comforts of civilization, and go naked. Ex-Lieutenant Boeter intends to buy a large tract of land in the Sandwich Islands, or, perhaps, a small island outright, for the purpose of founding a colony.

POST-GRADUATE MEDICAL STUDY ABROAD.[1]

By ANDREW MacFARLANE, M.D.,

INSTRUCTOR IN PHYSICAL DIAGNOSIS AND CLINICAL MICROSCOPY, ALBANY MEDICAL COLLEGE.

THE student of medicine on the eve of graduation looks forward eagerly, I am sure, to that crucial and final test—practice—which demands that he should competently employ the principles which he has learned, should exhibit the skill of which he claims to be the master, and which in return offers as a reward an honorable success. In his student days the mechanism of the human organism has gradually been spread before him, the mysteries of diseased conditions have been carefully, step by step, unfolded to him, and the potentialities of medicine have been impressed upon him so that all seems simple, clear, and logical. Unfortunately, the realities of practice bring their bitter realizations, and what seems plain and simple when sitting in the amphitheatre often appears dark as Erebus to the beginner standing by the bedside. Even that vast storehouse of vaunted remedies becomes at critical times the charnel house of our hopes, and diseased processes frequently, much to our surprise and at times to our chagrin, assume unexpected phases. This inevitable result is due to the fact that the mind of the student has of necessity been impressed with clear-cut pictures of distinct disease-entities, illustrated by carefully selected cases exhibiting definite types and none of the vagaries of disease. Actual practice, however, is very different, and our patients rarely show the classical pictures of disease. Mistake after mistake will, therefore, be made, and must be recognized before that training which is essential to satisfactory medical work is secured.

The important question, then, is, how is that training best obtained? Undoubtedly the best way is by service in a good hospital, where, under a competent visiting staff, the house physician has abundant opportunity to see and examine patients, watch carefully the course of disease, study closely each individual symptom, and, what is most important, assumes to a very large extent the responsibility for the care of the patient and meets the many emergencies which arise during his term of service, all of which is a most valuable preparation for private practice.

Fortunately our hospitals need no chanticleer to sound their praises. Each of you has had frequent opportunity to see the richness of the clinical material and the value of the services.

To-day, therefore, I shall cursorily speak of the training secured by special post-graduate study which some of you may undertake after your hospital work and others after a few years of private practice. The question naturally arises, where can such work be done most satisfactorily and at the least cost?

Teachers in the large centres of population have recognized this need, and to-day there are flourishing schools for practitioners in New York, Philadelphia, Boston, and in some of the Western cities. The advantages of these native post-graduate schools are that they are accessible, no foreign language must be mastered, the work is especially arranged to meet the needs of the American practitioner, and the physician can easily, without great loss, leave his practice for two or three months to brush up on any special line in which he feels he is weak. The disadvantages are that no large hospitals are attached to these schools, the teaching is to a great extent done with dispensary patients, who are necessarily somewhat unsatisfactory, and with American patients who do not take kindly to thorough examinations by classes.

It has been customary, however, for many American medical students to continue their studies abroad, especially in German-speaking countries. Little need be said of the medical work in Great Britain and France, London and Paris, though great medical centres offer little to the American practitioner. As the hospitals are scattered, much time is lost in going from one to the other, and

[1] A talk given to the Senior Class of the Albany Medical College.

private instruction, as it exists in Vienna, is practically unknown. To the specialist who has mastered the groundwork of his own field, and who is able to fully appreciate cases without instruction, the abundant clinical material of London and Paris is of inestimable value.

It will be well, I think, before describing the character of the medical work in Germany, to consider briefly the German university, and to note in what respects it differs from a similar American institution. Nothing in Germany impressed me so much as the large number of great universities whose fame rests not upon huge piles of stone and mortar, but upon the scholarship and scientific attainments of the men connected with them. Germany, a country only four times the size of the State of New York, has twenty universities, any one of which is sufficient to make a nation famous for scholarship. These universities are state institutions, endowed and controlled by the Government, having similar requirements for entrance, and covering exactly the same ground. The German university differs essentially from the American in that it is purely a professional school, and in no sense of the word "a college." Students before entrance must have graduated from the gymnasium, where the course of instruction has been carried to what would be equivalent to the end of the sophomore year in an average American college. Here the discipline is most rigid and severe, the instruction thorough, and the work practically the same in all the gymnasia. In the university all is changed, and the greatest latitude is allowed the student in his course of instruction and in his attendance upon lectures. The student enters the university to study history, philosophy, letters, theology, medicine, law, etc., because in Germany all candidates for the higher Government service, all teachers in academies, and all professional people, must have had an university training or its equivalent. The student is supposed at his age of entrance, twenty, or more, to know what his life occupation will be, and, therefore, the line of work he wishes to pursue. He accordingly matriculates, pays for, and attends lecturers only upon subjects leading to the end he is seeking. There are no recitations, no calling of the roll, and it is usually a matter of supreme indifference to the professor whether the student attends regularly or not his lectures. The student has a lecture-sheet signed at the end of the term by the professor, and this is the official evidence of attendance at the requisite number of courses of lectures when he comes up for a degree. After having attended the required number of courses of lectures, as shown by his lecture-sheet, the student may try the examination for a degree. For this he has to write a thesis, which he must defend before a committee of the faculty, and in addition prove a number of scientific propositions propounded by them. The severity of the examination is evident from the fact that outside the professions not more than ten per cent. of the students take their degrees. This can be explained, however, to some extent, by the fact that all must, in addition, pass state examinations. As the university degrees are purely honorary, and somewhat expensive, many do not seek them.

The teaching body in a German university consists of the "ordentlicher Professoren," full professors, "ausserordentlicher Professoren," somewhat similar to our adjunct professors, though entirely independent, and the "privat-docenten." The "privat-docenten" need a word of description, as they are characteristic of the German university and play an important part in the instruction of the American medical students. They are young men, thirty to forty years of age, distinguished for scholarship, which has been tested by special examinations involving original research and extensive study. They are permitted, after having thus shown unusual ability, to deliver courses of lectures under the ægis of the university. They receive no salary from the university except the fees of the students who attend their lectures. It is therefore necessary for them either to lecture upon some subject not covered by a professor, or to deliver lectures more attractive than those of the professor.

The professors, adjunct professors, and instructors announce at the beginning of each term (the winter term extends from October 15th to March 15th, and the summer term from April 15th to August 15th) the subjects of their lectures for the ensuing term, and the student selects those which he wishes to hear.

Each professor and instructor lectures upon the subject in which he is most interested, and with which he is therefore most familiar, and regards himself not as one intended to insist upon attendance, to maintain discipline, or to compel students to work, but as a teacher, *i.e.*, one who professes certain opinions, a leader in thought in his field of work, and who is there to direct, clear the way, and incite students to earnest effort in the work in which they are engaged. As there may be, and often are, lectures delivered by the professors, the adjunct professors, and the instructors on the same or kindred subjects, it behooves the professor to keep abreast of the times in his lectures, making them attractive as well as deeply scientific, or he will find his lecture-room deserted for the more brilliant lectures of a young privat-docent.

The adjunct professors and privat-docenten are incited to advanced and original work to attract the attention of that most severe of critics, the scientific world, and thus receive an appointment to a higher position either in their own or in another German university. Another factor in stimulating the professors to a high standard of work is the fact that students rarely complete their course in one university but study in several, courses of lectures taken in one university being accepted in every other. Thus a medical student might study histology and pathology in Freiburg where Ziegler is, obstetrics in Munich under Winckel, medicine in Heidelberg listening to Erb, in Erlangen to Strümpell, or in Berlin under Leyden, Senator, or Gerhardt, and surgery in the same university or elsewhere. This change from one university to another is, I believe, more common among non-medical students, but is still quite frequent among medical students.

The key-note of the German university is freedom in teaching and liberty in learning. This eternal principle, which has made Anglo-Saxon governments and civilizations the most advanced in the world, has given to German intellectual life its present pre eminent position and has elevated its university system to a plane far above that of any other country.

Briefly, then, what is the effect of this system upon the university, and what is the result upon the students? It makes every man completely independent in everything—mode of living, personal behavior, course of instruction. It offers the student complete courses of lectures and abundant opportunity for advanced work on any university subject which he may take or not as he pleases. The result is that there are the two extremes among the students—the workers, who avail themselves of the opportunities afforded, and the others—the dawdlers, the lazy, and the mentally incompetent, who simply idle away their time and fritter their opportunities.

The American college contains exactly the same human elements, as nature is much the same everywhere. With us, however, the attempt is made to get a fair average, and the bright, hard working students are to a great extent held back by the lazy and incompetent, with the result that the best students do not do as much work as they might, while, I am afraid, very little good is accomplished with the others. All of us, I am sure, know many men, utterly incompetent, who have received college degrees for which they did no equivalent work. This same principle of instruction is carried out in the medical schools, modified by the special requirements of the work—laboratory instruction, clinical examination of patients, surgical technique, etc. It is not necessary to speak in detail of the German medical schools; that would require too much time, and in your case is of no special value except in so far as relates to the work that American physicians can satisfactorily do in them.

We shall therefore speak only of post-graduate medi-

cal work, and shall divide the German medical schools artificially into the large medical centres, as Vienna and Berlin, and the smaller, as Heidelberg, Freiburg, Würzburg, etc. The advantages of the smaller university are that living is cheap, tuition is low, and the student enters directly into the German life, and thus has an excellent opportunity to master the German language. The disadvantage is that outside of laboratory work you can get no special instruction, and must take the ordinary lectures and regular instruction given to the students. This, while very good, is not quite what is sought by the American physician, who desires to crowd as much clinical work as possible into a few months. In the laboratories, however, there is always plenty of material, and much work can be done alone with a little help from the professor or his assistants. The advantages of the large medical centres, especially Vienna, are the vast amount of clinical material which can be used, and the special instruction in every subject which can be obtained from trained and well equipped instructors.

The pre-eminence of Vienna as a medical centre is due to its large general hospital. This is, I believe, the largest hospital in the world, and contains about four thousand beds. There are within its walls about ten thousand births a year, and ten to twelve autopsies are made daily in its pathological institute. With a staff of twenty-four full professors, thirty-eight adjunct professors, sixty-two privat docenten, and a large number of trained assistants, it has a teaching body and clinical material unequalled in the world.

The American medical student goes to Vienna not for the ordinary lecture and laboratory work but to receive special training, which is to a great extent especially arranged for him by the privat-docenten and assistants. The privat-docenten receive nothing, the assistants a mere pittance from the hospital. They do not engage in private practice but busy themselves with special investigations and advanced work in the hospital, with the hope that some day they may be called to a professorship in Vienna or in one of the smaller Austrian universities. As they must earn money in some way while waiting, they are allowed to use the clinical material for purposes of demonstration in private courses. These courses are to a great extent arranged to attract the Americans, as they are the foreigners most lavish with their money.

Probably the most satisfactory courses given in Vienna are those on medical diagnosis, and this is due not only to the instruction, but even more to the vast amount of clinical material offered for investigation.

There are in the general hospital about fifteen hundred medical patients; of these all the difficult, unusual, and obscure cases are sent to the wards under the charge of the teaching professors, who have each about one hundred and fifty patients in their divisions. The great mass of ordinary uninteresting cases are placed in wards under the care of non teaching professors. Patients also are frequently transferred from wards under the charge of a teaching professor to other wards when the disease has been thoroughly studied and demonstrated.

The assistants of the teaching professors having this magnificent clinical material are the men who give the valuable courses in medical diagnosis. The members of a course, usually limited to six, go to the wards at a fixed hour, and on a class list find what patient has been assigned to each member of the class. Every man then thoroughly examines his patient for an hour, when the assistant comes and calls on a member of the class to demonstrate his case. He stands at one side of the head of the bed, the assistant at the other, while the rest of the class are grouped about the bed. The demonstrator must give a complete and exact diagnosis, then make a thorough, systematic physical examination, the deductions from which are confirmed, modified, or corrected in every detail by the assistant. After the examination the assistant goes rapidly over the case; grouping together logically the symptoms, making clear the obscure points, discussing the differential diagnosis, and speaking a little about the treatment, though this is usually their weak point. Two such cases are demonstrated every day, and two new cases added, so that each case demonstrated has been thoroughly examined by every member of the class. The value of this work depends upon several factors. First, the cases are all difficult and interesting, selected from a large number, each one of which has been carefully studied for the regular lectures of the professor. Secondly, the patients are exceedingly submissive and rarely object to thorough physical examinations, even when they cause great pain. Thirdly, the instructor is a splendid diagnostician, one who is seeking by his work to create such a reputation that he will be called to a professorship. One of the men under whom I worked was at that time—1891–92—reputed to be the best diagnostician in Vienna, and since then has been appointed a professor in the university. Fourth, the men doing the work are imbued with the true spirit of scholarship, seeking knowledge not in order to pass examinations and to receive degrees, but because of its own intrinsic value. In much the same way courses on other subjects are given, modified by the special character of the subject.

These courses range in cost from 15 to 30 guldens for thirty lessons, a gulden being about 43 cents. The best courses are all about a gulden a lesson, while a very few courses on diagnostic gynecology and operative gynecology on the cadaver cost usually 50 guldens for twenty-four lessons, but in such cases the class is generally limited to four.

One rarely takes less than five courses a day, or more than seven, for which the tuition will range from $9 to $12 per week. The usual method of living is to hire a room by the month, where a light breakfast is obtained, and to take the other meals at a restaurant. One can, however, if desired, secure a room and full board at a fixed price in a "pension." The cost of living depends largely on the personal factor and varies with one's tastes. Some live decently, with economy, for about $24 per month, while others spend, without extravagance, easily, twice that amount. Fair limits per month for absolute expenses, tuition, and board, range from $60 to $100. There are, in addition to this sum, the incidentals—opera, concerts, baths, and personal expenses—which would increase the cost of living from $75 to $150 per month.

The first amount is low, but not the lowest possible, though it is as low as it should be, as one should not neglect to go to the opera and concerts; while the second is a fair allowance, but not at all extravagant.

In Berlin there are no courses given which are just the same as those in Vienna. There are special courses in the spring vacation and just before the winter semester. These last four weeks, and often contain very many members, rendering much individual instruction impossible. During the semesters the assistants are not allowed to use the ward patients for private instruction.

The questions now arise as to the knowledge of German necessary for satisfactory medical work, whether a sufficient acquaintance with the language should first be secured before medical work is begun, or if both may not be pursued at the same time.

Vienna is the only German city where medical courses to any extent are given in English; but these courses are generally the poorer ones, while the best are usually given only in German. Explanations given in English by one having a meagre knowledge of the language are not, as a rule, I think, so satisfactory as when given in German, even if the German of the auditor is decidedly limited.

It may be well to sketch out, rather vaguely of course, a stay of a year to a year and a half abroad, and one of only six or seven months.

In either case as much German as possible should be learned before starting, and it would be wise to read some standard German medical work, as that of Strümpell. If an extended stay is planned, it would be best,

I believe, to spend the first three or four months in a small university town, as Heidelberg, Göttingen, Freiburg, etc. Here the knowledge of the German language should be the first desideratum, while laboratory work and attendance upon clinical lectures would be valuable as German lessons and in teaching German methods of procedure and examinations.

Then, when German verbs were no longer a nightmare, and German construction a hopeless labyrinth, Vienna should be the objective point. Here the specialist in embryo could spend eight or nine months; then, later, two months each in Berlin, Paris, and London, seeing famous men, studying their methods and examining their enormous material. For one who can spare only six or seven months abroad, I believe the result will be better if he gives the first month exclusively to German in some small German town, where there are no temptations to speak English, then go to Vienna, rather than to proceed directly to Vienna. The thought no doubt arises why cannot German be studied in Vienna, the physician taking at first English courses, then, as his acquaintance with German increases, taking those given in German. This can be and is done by a number, but, I believe, not at all successfully.

The temptations to speak English in Vienna are so great that I doubt if any American medical student, except by the greatest self-denial and control, ever learns in Vienna very much German.

The Americans there are so numerous that they of themselves form a little society; they have their church and their social organization, and, as these special courses are almost entirely taken by Americans, all with whom they are thrown in contact are American. One rarely becomes acquainted with the German students in a large university, and thus has little opportunity of learning from them.

The cost of a stay for six months need not, with economy, be more than $450, with $200 additional for the journey to and fro. For a year it can with economy be done for $900, including the journey. If a microscope, instruments, books, and clothes should be bought, or extensive pleasure-trips undertaken, the total would necessarily be much increased.

The best time to go to Vienna is in the spring, April and May. Many Americans, who have studied all winter, leave Vienna at this time, either to return home or to continue work elsewhere; on this account it is much easier to get into the best courses, and this is especially the case if you have a friend in Vienna who will prearrange work for you. Medical work in Vienna is regulated by the ordinary commercial laws of supply and demand, and as the number of Americans is usually very large, epecially in the fall and winter, and the number of desirable courses limited, there is an eagerness to get for one's self and one's friends the best, while others have often to wait for months for the same openings.

It is, however, always an easy thing to start into satisfactory work in Vienna. The Anglo-American Medical Association, whose secretary, the Rev. Mr. Gordon, has done incalculable kindnesses to English-speaking students, gives to new-comers most valuable information as to rooms, board, courses, etc., and introduces them to the older men, who are usually kind in putting the new-comer on the right track.

I cannot bring this short and desultory talk to a close without saying a word about the German professor. You can only become intimate with him in one of the smaller universities; but such an acquaintance is of itself worth a stay at a small university. His kindly welcome to Americans, his hearty greeting "Herr College," and his willing assistance to the earnest student make the stranger feel completely at home. If it be your good fortune, as it has been mine, to make excursions with him, you will find a union of unaffected simplicity and true greatness which will be a remembrance to be cherished, and an ideal to be sought after during the remainder of your lives.

A CASE OF INSANITY DUE TO THE MENSTRUAL FUNCTION — OÖPHORECTOMY — RECOVERY.

By ELIOT GORTON, M.D.,

ASSISTANT PHYSICIAN TO THE NEW JERSEY STATE HOSPITAL, MORRIS PLAINS, N. J.

In the *Medical News* of May 20, 1893, appeared an article from the pen of Dr. B. D. Evans, Medical Director of the New Jersey State Hospital at Morris Plains, on "Periodic Insanity in which the Exciting Cause Appears to be the Menstrual Function." The doctor closes the article by drawing a few deductions from the case he relates, of which the following is a synopsis: "That in many cases of periodic insanity the exciting cause may be directly traceable to the menstrual function; and, when the attacks are coincident with the catamenial flow, and an apparently normal mental condition prevails between the menstrual periods, removal of the ovaries is justifiable even though there be no pathologic lesion." He cites a case of insanity of eight years' duration, which attained to perfect mental and physical health after oöphorectomy, and it is the purpose of this article to add another case to the literature of the subject, my own views being in perfect harmony with the sentiments above elucidated. The following case is interesting and instructive from every point of view, and not only supports the above deductions, but in its result contains much food for reflection.

The case to be related is that of a young school-girl, aged sixteen, who, when well, was inclined to be very sociable, lively, and even-tempered. Hereditary history of a maternal grand-aunt who died insane. Menstruation had been regular and normal. She was admitted to this hospital on March 23, 1893, with the following history:

She had been attending school until the latter part of September, 1892, when she became very much interested in her spiritual welfare and became converted. Shortly after joining the church her mother noticed that she was not at all like her former self. From a lively, sociable, bright girl she became moody, irritable, worried, and depressed. When questioned by her mother she admitted that it was the weight of her sins that was troubling her.

This condition of depression steadily increased until at Christmas-time, after having on several occasions threatened suicide, she passed into a semi-stuporous state, eating but little and sleeping practically not at all. She remained in this state of stupor for three weeks, when she suddenly began to improve. The improvement, however, was but temporary and of short duration. She again lapsed into a state of depression, but not so profound as in the preceding attack, and, apparently about to recover, she passed suddenly into so violent a stage of mania as to render restraint imperative. At this time she attempted to kill her mother and sister, and succeeded in wrecking much household furniture. Three weeks after this maniacal outbreak she was brought to this hospital.

On admission she was very quiet and lady-like, talked in a rational and consistent manner, and had the appearance of being a thoroughly well girl, both physically and mentally. She was, however, placed under careful observation, but gave no evidence of mental instability until the approach of the menstrual epoch, the latter part of April. As the flow commenced she became profoundly depressed, refused to talk or eat, and for several days was fed with a nasal tube. From this period of depression she recovered in time to pass into a period of exaltation as the June menstrual period approached. She continued in a state of excitement for two weeks, and it is from this time onward that the regular periodicity seems to have become established. Every month thereafter, for a few days preceding and following her menstrual period, she became greatly excited and erotic. Her language during these periods was offensively obscene and profane; her self control was entirely abol-

ished, and she exhibited many delusions, chiefly of an erotic character.

These periods usually were of about ten days' duration, and, as the menstrual flow ceased she began to improve, and in a few days would be apparently well. Then she was extremely reluctant to discuss her former condition, and any questioning in regard to it embarrassed her greatly. She was perfectly cognizant of all that happened during the cycle through which she had passed, and the fact that it was a source of much anxiety and mortification to her, would indicate that she looked back upon her actions and speech from a comparatively sane stand point. To her it was incomprehensible, and she begged to be made well.

In December, 1893, she was subjected to a vaginal examination, with negative results. The ovaries and tubes were apparently in a normal condition, but there was a slight tendency to anteversion on the part of the uterus. During the examination the absence of tenderness was especially noted and commented upon.

February 1, 1894, immediately following cessation of menstruation and consequent return to mental health, she was removed to the Mount Sinai Hospital in New York City, and on February 3d was operated upon by Dr. Brettauer, who removed both ovaries and tubes. With the exception that the left ovary contained a small cyst, the appendages were normal. She made a rapid and uninterrupted recovery from the operation, and at no time did her temperature rise above 100° F.

February 19th she was again returned to our care in excellent physical and mental condition, quiet, rational, and with the abdominal wound entirely healed. For one week after her return she remained quiet and orderly, with normal pulse and temperature.

February 26th, when she should have menstruated, she manifested a tendency to exaltation with a decided erotic impulse. She destroyed a pair of drawers and threw them down the closet. Her movements were so abrupt and nervous as to almost simulate chorea. In her talk she was rational, but inclined to be saucy and irrelevant. This period lasted but three days, and was the last evidence of mental instability she ever presented to us.

At our request she was taken home by her mother on May 31st last, but before leaving was thoroughly and carefully examined. The parts were apparently in a perfectly normal condition, with no evidence of any adhesions or signs of hernia. The scar on abdomen was not at all tender and there was no soreness anywhere.

At the present writing, five months after operation, she has remained perfectly well, mentally and physically, and has not shown the slightest tendency to a return of her abnormal mental condition.

In this case the operation was performed as a *dernier ressort*, and as embodying the only hope the patient had of escaping, not only from her periodical paroxysms, but from that condition from which no mind returns, and into which she was rapidly drifting—dementia. The operation intervened, a serious one it is true, but the patient survived, and is now, and probably will continue to be, a useful member of society. Still, had she died under the knife of the surgeon, will anyone contend that it would not have been better so, than that she should have become a hopelessly demented atom of humanity, and a life-long charge upon the State or her friends?

This case differs from others which have been reported, in that the period of excitement seemed to come on as a result of the preparatory evolution incident to and preceding the menstrual flow. Whether this is due to the congestion which is claimed by competent authorities to always precede this function, is a point to be determined, but to my mind it is conclusive. It is also worthy of note that three days after the flow had become established there was an appreciable lessening of cerebral and motor excitement. This in itself would tend to confirm the opinion that congestion of the parts, concomitant pressure on nerve-supply, and consequent reflex irritation as a result of increased blood-pressure, is at least a factor in causation.

We cannot fail to be impressed by the many and varied psychic disturbances which occur in sane women at the menstrual period, not alone in the delicate and sickly, but in the more robust. When we take into consideration the intimate relation of the brain with every other organ in the body by reason of its direct and reflex connections, it can readily be appreciated how much greater must be the strain in those who are afflicted with a neurotic diathesis. It is, therefore, not a matter of theory, but a matter of fact, that the menstrual function exerts a most potent influence upon the nervous system of woman. Why in some it should be so much more severe than in others, and become in itself an element of shock or stress so great as to dethrone reason, can only be conjectured. No two organizations are precisely similar, and so many other elements, such as physical health, environments, heredity, etc., must be taken into consideration, that in many cases of insanity where menstruation is normally performed, it is well nigh impossible to say with any degree of certainty that this function is the cause, pure and simple, of the insanity.

Admitting, however, that in the cases under consideration the menstrual function is simply the exciting cause, where this function exerts so profound an impression upon the nervous protoplasm as to induce insanity; where, instead of acting as a "safety-valve" it becomes the cause of mental explosion; then it is, in my opinion, the imperative duty of the physician to advise the artificial production of the menopause. Especially will this obtain in those cases in which the cause may be directly traced to disorders of menstruation, and in which there is an hereditary taint.

And in this connection let me quote a few lines from Bevan-Lewis. He says, "Given an organism predisposed by inheritance to insanity, such predisposition will tell with special force at periods of reproduction and development."

I am not one of those who hold the sexual organs of woman responsible for the majority of her ills, and I deprecate as much as anyone the abuse of abdominal section. I maintain, however, that death is preferable to chronic insanity, and in view of the remarkable and brilliant successes achieved by the surgeon along this line, I am convinced that we have a field which has been but little explored, and one which offers bright inducements as regards the cure of insanity by the removal of the cause; and I need only add that the consensus of opinion of many well-known writers confirms the statement that the menstrual function is the cause of insanity in a large number of cases. Pozzi says "the sexual apparatus is not, so to speak, an accessory wheel in the female mechanism; it is, on the contrary, the chief wheel, and it is to secure its proper action that constant economies and reserves are made by nature."

Dr. George H. Rohe, in an article considering the legal aspect of this subject, published in the *Medical and Surgical Reporter* of July 15, 1893, reports the result of twenty-two oöphorectomies embracing different forms of insanity. There were twenty physical recoveries and two deaths. Of this number four made an absolute, and three a partial, mental recovery. In seven there was decided mental improvement.

I am confident that I have seen several cases become hopelessly demented, or so deteriorated mentally as to be beyond medical or surgical aid, which, had ovariotomy been performed, would have recovered their reason. There are cases under observation to-day which I am positive would be greatly benefited, if not permanently restored mentally, by such an operation.

Under these circumstances it seems to me that it ceases to be a question of whether or not oöphorectomy is justifiable.

I maintain that it should be done in all those cases in which the menstrual epoch acts as the exciting cause of insanity, and the earlier the operation is performed the better for the patient and for posterity.

TREPHINING THE FRONTAL BONE FOR CHRONIC HEADACHE.[1]

By J. MARSHALL HAWKES, M.D.,

NEW YORK.

GENTLEMEN:—The case which I am about to present to you, I am sure will prove interesting; for while the affection is rare, when we do find it its incurability is exasperating. Moreover, it is in a comparatively new field of surgery, and, still more important, the treatment in this and two other reported cases has been entirely successful.

On June 31, 1891, Mr. M——, aged twenty-eight, applied to the writer for relief from headache of twenty years' duration.

The history of the case is as follows: When eight years old, while playing in a yard in the downtown tenement-house district, he fell on a curbstone and received a cut in the upper right quadrant of the forehead, about an inch above the supra-orbital ridge and parallel with it. His mother took him to the nearest druggist and had the cut dressed with adhesive plaster, after the manner of the time. The cut suppurated and healed slowly. He soon began to suffer from headaches in the upper right frontal region. They increased in severity during his youth and young manhood, until they became quite unbearable. Indeed, he was unfitted for work at least one day in the week, and frequently for two days. These headaches were practically continuous. If he awoke in the night he felt the pain, and it was subject to frequent exacerbations, accompanied by "attacks," as he termed them. These attacks consisted of a severe paroxysm of pain, accompanied by dizziness, making him feel very weak, so that he would usually, though not always, fall wherever he happened to be.

At no time during these attacks did he have a convulsion or even a slight convulsive twitching. He was never unconscious, always knowing everyone about him. He never vomited, nor bit his tongue or cheek; he never hurt himself when he fell, nor did he ever fall in a dangerous place, though he frequently remarked to his friends that it was strange that he did not. He always had a premonition of an attack. No exciting causes were apparent, though he declares if the wind blew hard in his face the headache would become worse. He had them when a boy in school and after he began to work. Again and again he had to be led home by his fellow-workmen or sent home in a carriage. He had no more "attacks" when he was working than when he was not. He had never had any illness, not even measles.

The treatment of various physicians and attendance at two of the city hospitals for varying lengths of time, had not produced any amelioration of his condition, and, at the time he came to me, his condition so preyed upon his mind that he feared he would become insane.

On examining his head in the region above indicated, a small indentation, scarcely an eighth of an inch in length and of only slight depth, was found, and it was only after questioning the patient at great length that he remembered exactly when he received the injury as above elicited, though he was positive of his age (eight) at which the headaches began.

Since the accident had happened so long a time before, and because the writer could learn so little of his previous history, it was deemed only prudent to eliminate the various other causes of headache, such as eye-strain, stomachic derangement, disease of the kidney, etc. He was therefore sent to Dr. Knapp, who examined his eyes and found them both normal. He was dieted most rigorously on milk and the whites of eggs for some time, without any relief.

As no trouble could be found and all medical treatment was unavailing, the impression became more and more fixed that the inner table of the frontal bone had been fractured, and that the resulting exostosis, or possibly a pacchionian granulation pressing on the brain, was the probable cause, and that trephining might give him relief; certainly nothing else would. He readily consented, and on July 30, 1891, a semicircular incision was made surrounding the scar tissue marking the seat of the accident. When the scalp was turned back there was seen to be a slight depression in the skull not over half an inch in length. Following the surgical indication, the trephine point was placed in the centre of this depression and a disk of bone, three quarters of an inch in diameter, was removed. On examination, this disk was found slightly thickened at its upper margin, where normally it should have been slightly thinner. There was, however, no well-defined mark of fracture. As the dura mater appeared perfectly normal, there was no call for further search. The trephine hole was carefully burnished, every rough particle being removed, so as to leave no possible chance for irritation. The scalp wound was then carefully sutured with black, iron-dyed silk; no drainage was deemed necessary.

In five days the stitches in the integument, thirty-seven in number, were removed. At the first dressing, on removing the bandage, release of the pressure caused the patient to have a slight epileptiform seizure; the twitching of the body was general. Conjecturing that the sudden removal of pressure was the probable cause of the trouble, gentle pressure was made upon the area representing the uncovered portion of the brain, and at once the spasm ceased. The wound united promptly and in seven days the patient was on the street.

From the moment of etherization until now, the patient has had no headache. He expresses himself as very much delighted with the result. He goes so far as to say that he is "beginning life anew."

The hole in the skull has nearly filled with a fairly dense fibrous tissue, through the centre of which, however, the pulsation of the brain can still be seen and felt.

On looking over the literature of the subject, I find only two similar cases reported; one by Mr. Horseley, of London, and the other by Dr. Robert F. Weir of this city. Reference is made to both these cases in Dr. M. Allen Starr's "Brain Surgery," page 272. In these two cases there is a history of a blow, but there was no sign of fracture in either of them.

As to the indications for trephining for chronic headache, Mr. Horseley thinks (and it appears to be the general consensus of opinion) that "it is justifiable to trephine in every case where the pain is persistent, localized, and has resisted all medical treatment, whether there be any fracture or not."

Occasionally, after blows on the head without fracture, there will develop pacchionian granulations, which in themselves may cause the persistent headache.

In virtue of the extremely low mortality from a carefully performed trephining, there seems to me to be no contra-indication to the operation as a last resort in cases of the above character.

1343 LEXINGTON AVENUE.

[1] Read at the June, 1894, meeting of the New York County Medical Association.

Dr. Eduard Sperk died a short time ago in St. Petersburg. He was one of the leading physicians of Russia at the time of his death. The first twelve years of his professional life were passed in Eastern Siberia, where he was government physician and afterward medical inspector. In 1870 he was recalled to the capital to take charge as physician-in-chief of the Kalinkin Hospital. He devoted much time to the study of prostitution, and had written much on the subject.

Spring Knee.—Dr. Delorme describes, in the *Gazette des Hôpitaux*, No. 42, 1894, a condition in the knee similar in its general features to the well-known spring finger. Just before full extension of the joint is reached there is a slight hitch, and then the limb straightens itself with a sharp, rather painful jerk. Locomotion is in consequence rendered uncertain and painful. In the case observed by the author upon which his description was based, the interference with free extension occurred only when the patient was on his feet.

Progress of Medical Science.

The Coexistence of Infectious Diseases.—Dr. Caiger, at a recent meeting of the Epidemiological Society, presented a study on the coexistence or close succession of two or more infectious diseases in the same individual. His experience at Stockwell, he said, had satisfied him that such concurrence of infections was as frequent as mere probabilities would explain, and that, so far from affording protection against other diseases, some certainly increased the susceptibility thereto. (*The American Journal of the Medical Sciences.*) In the last four years he had seen 362 cases of two and 17 of three diseases running some parts of their courses concurrently; in 200 of these the acute febrile stages of two or three coincided. The priority of the several diseases was calculated from their known incubation periods. The primary disease was scarlatina in 197, which was complicated by diphtheria in 97 cases, varicella in 43, measles in 31, whooping-cough in 13, erysipelas in 10, enteric fever in 2, and typhus in 1. Scarlatina was a complication in no fewer than 88 among 97 in which the primary disease was diphtheria; in 20 among 23 of varicella; in 14 of 17 of whooping cough; in 6 of 9 of enteric, and 9 of 18 of measles, though here diphtheria accounted for another 7. Among the 17 triple attacks scarlatina was the primary disease in 9, and a complication in 4 only, diphtheria holding the highest place with 9. During the past six years, 48,367 cases of scarlatina had been admitted into the hospitals of the Asylums Board; of these 3,166, or 6.54 per cent., were complicated, 1,094 with diphtheria, 899 with varicella, 703 with measles, and 404 with whooping-cough; the relative numbers of diphtheria and whooping-cough being probably owing to the fact that many had already had whooping-cough in infancy, while diphtheria, though less frequent, might and often did recur; these four diseases accounted for 3,100, or all but 66. The questions suggested by these figures were: 1, Did any disease render the individual less or more susceptible to infection by another? 2, Did the primary disease in any way influence the course or character of the secondary one as regards (*a*) incubation, eruption, etc., periods; (*b*) severity of the disease; (*c*) distribution of local phenomena; (*d*) liability to sequelæ and other complications? The conclusions at which he arrived, after eliminating the influence of age incidence, seasonal prevalence, actual frequency, etc., were first, that there was no such thing as antagonism between any, but rather the reverse, increased susceptibility being brought about, generally or locally; that is, first, by the lessened power of resistance induced by a disease attended with grave constitutional disturbance; and, secondly, by the local inflammations facilitating the development of the contagia of diseases known to affect the mucous membranes or tissues in question. Thus, an attack of varicella exerted no influence on any that might follow, but when scarlet fever was the primary disease, varicella, favored also by the quasi-dermatitis left behind, might rival unmitigated small-pox in intensity of fever and extent of eruption. Scarlatina was frequent and dangerous after diphtheria, but diphtheria following scarlatina was still graver, since the scarlatinal throat, teeming with staphylococci and streptococci, was a perfect soil for the bacillus of Loeffler. So, too, while the general phenomena of measles might be aggravated by previous diphtheria or scarlatina, and in the latter conjunction the rash would be intensified, an attack of diphtheria following on measles was even graver than the post-scarlatinal, since it inevitably attacked the larynx and trachea, and tracheotomy was very rarely of any avail. Measles and whooping-cough were known to follow one another, or to coexist, mutually increasing the susceptibility of the individual. The author had never found the incubation period of a disease affected, but the presence of scarlatina accelerated the appearance of the rash in measles by a couple of days.

Cystitis in Patients who Have never Had an Instrument Passed.—Since it has been recognized that all cases of cystitis are the result of infection, the catheter has been regarded as the only method by which the infection of the bladder takes place. While this method ranks first in importance, it is important to bear in mind that, apart from tuberculosis, cystitis may and does occur in individuals who have never been catheterized, and who have never had either a urethritis or infective disease of the kidney. According to Dr. Reymond, one not uncommonly meets with cases, usually advanced in life, the subjects of enlargement of the prostate, who have never been catheterized, and who have never had symptoms pointing to infective disease of the kidney; in whom, however, there are symptoms of cystitis, and the urine contains pus and micro organisms. Where does the infection come from? Whence are the organisms derived? Bacteriological examination of the urine in seventeen cases showed that the bacterium coli commune was present in seven, and that other microbes were present in ten. The latter were such as are normally met with in the urethra, and it is assumed that they reached the bladder by a simple extension backward, the conditions which enabled them to lodge and give rise to cystitis being the residual urine in cases of prostatic enlargement. Those in which the bacterium coli commune was found were more acute in their clinical features. Of the three possible routes by which they entered the bladder, the urethra and ureter were regarded as unlikely. The author believed that they might have passed from the rectum and through the prostate.—*Annales des Maladies des Organes Genito-Urinaires.*

The Dangers of the Long Rectal Tube.—The use of the long rectal tube in obstruction of the bowel has never been looked upon with favor by anatomists. Nothing is more difficult than the successful manœuvring of the rectal tube through the turns of the sigmoid flexure. The question of the value and safety of this tube having been asked of the *British Medical Journal*, the matter was referred to Mr. Harrison Cripps, who replied as follows: Traditions die hard, and notwithstanding the condemnation of the long rectal tube by Brodie, Treves, and many other eminent authorities, I still find that in most cases of obstruction or supposed obstruction the tube has been introduced. Fortunately these tubes are fairly soft, so that in a capacious rectum, when they impinge and are arrested about opposite the promontory of the sacrum, they simply coil up and do no harm. If stiffer ones are used the patient's life is placed in imminent risk. A patient at St. Bartholomew's Hospital was to be operated on for ruptured perineum. In order to increase the supposed efficacy of the injection, a quart of soap and water, with some ounces of oil, were injected by means of a long tube. The injection never returned. A few hours afterward, owing to the acute symptoms of the patient, I assisted one of my colleagues in opening the abdomen. The soap and water and oil we found in the abdominal cavity, and a hole below a reduplicated fold in the upper part of the rectum. The patient died. The idea that these tubes can be generally passed into and beyond the sigmoid flexure is a pure delusion, save in the rarest circumstances. As a means of diagnosis, or of treating stricture beyond the reach of the finger, tubes of any kind are absolutely useless. If a stricture is actually present it would be 100 to 1 against the long tube or bougie entering it, for it would almost certainly catch in the cul-de-sac generally caused by the invagination of the stricture. If a stricture be not present, the arrest of the bougie by the sacral promontory leads to delusive diagnosis. Brodie, in his lectures, alludes to a case in which a worthy practitioner had spent over 150 hours in dilating a supposed stricture situated high up. The treatment had extended over a period of a year. Brodie, who was present at the post-mortem examination, found there was no sign of a stricture, the bougie becoming arrested by a curve of the sacrum.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street

New York, August 25, 1894.

A PLEA FOR PUBLIC ANÆSTHETIZERS.

To an observant spectator of operations in our hospitals it is a matter for surprise and wonder that fatal accidents so rarely result during the administration of anæsthetics. No stronger argument could be furnished to the advocates of the use of ether in preference to that of chloroform than the fact that the former is recklessly administered in hundreds of instances by inexperienced anæsthetizers, yet without any immediate ill consequences. We use the word "immediate" advisedly, because we are convinced that not a few of the fatal cases of acute pulmonary and renal troubles which have followed ether-anæsthesia might have been avoided, not by substituting chloroform, but by administering ether in a proper manner, instead of saturating the patient with it. Strange as it would appear to an intelligent layman, hospital surgeons continue to delegate this important duty to junior assistants, dressers, and medical students, even in the most serious operations, in which the constant and skilful surveillance of the patient is a matter of vital consequence. Occasionally a serious lesson is given, but it is rarely heeded, until a sudden death on the table leads to a temporary reform.

We are not exaggerating when we affirm that the average junior interne does not take the trouble to make a scientific study of the variations in the pulse and respiration ratio, the changes in the pupils and muscular reflexes, etc., in a perfectly healthy subject, while the danger signals in the case of weak patients are often unheeded, or are not recognized until the close of a long operation, when the patient is in actual collapse. Then there is a hasty resort to powerful hypodermatic stimulation, strychnine, digitaline, or strophanthine, being repeated at dangerously short intervals, which would have been unnecessary if a hot saline enema containing whiskey had been given before or during the operation.

The entire responsibility of watching the pulse devolves upon a young fellow, fresh from the medical school, whose knowledge is almost entirely theoretical, however great may be his natural aptitude and powers of observation. The rest of the house-staff are expected to devote their attention entirely to the operation, and it must be admitted that the junior's mind is too often absorbed in its details.

The proper administration of ether is really an art which few men seem to acquire to perfection. Witness the annoyance so often experienced by surgeons in private operations, when, from courtesy or necessity, the administration of the anæsthetic is entrusted to the family physician, who, with the best of intentions, either pushes the anæsthetic to the limit of asphyxiation, or allows the patient to struggle and vomit.

We are far from asserting that the young gentlemen, who by their zeal and fidelity add so much to the pleasure and profit of our hospital services, do not in many instances become expert anæsthetizers, but this requires time, so that, as a rule, they have only become really proficient when they are replaced by green men. If this criticism applies to the giving of ether, how much more forcibly does it apply to the administration of chloroform! Doubtless this valuable anæsthetic would be employed much more frequently in New York than it is at present if surgeons had sufficient confidence in the skill and experience of the anæsthetizer. In our own experience we have substituted ether in cases in which chloroform was clearly indicated, simply because we did not feel justified in entrusting the more dangerous anæsthetic to one who was entirely ignorant of its physiological action. Personally we would almost prefer to run the risks of employing ether in a case of suspected renal or pulmonary trouble, than to incur the equal risks of having the patient killed by chloroform.

Now this state of things ought not to be allowed to continue. We believe that the time will come when every large hospital will have a regular salaried anæsthetizer, who will always be available, and who will enjoy the same confidence in his department as the pathologist does in his own. Operations will certainly proceed more smoothly and safely; we shall hear of fewer deaths from "heart failure;" and cases of "ether pneumonia," and of "acute uræmia from ether," will be almost unknown. The advantages to the operator will be immense. Instead of having his mind distracted by the struggles of a half-anæsthetized patient, or being obliged to stop his work until she is revived from a condition of asphyxia, he will be able to give his entire attention to the operation, relying on the anæsthetizer to note the danger signals, to administer stimulants when they are needed, and to keep him informed as to when he must hasten, or when he can proceed deliberately.

If the expense involved in the employment of a special anæsthetizer is an objection (and we admit that managing-boards are apt to prick up their ears at the mention of any extra outlay in the medical department), we suggest that a subscription-list might be started among the members of the medical board, all of whom will doubtless have, at some time, suffered from the results of the mal-administration of anæsthetics.

In closing we cannot refrain from alluding to a dangerous practice which we have noticed in some hospitals, that of allowing a nurse to hold the ether-cone while another patient is being anæsthetized. This is a dangerous custom (to which we plead guilty), and in the event of medico-legal investigations would be extremely difficult to justify in a court of law. As a fact, considerable stress was placed upon this point in the case of Dr. Mary Dixon-Jones *vs.* the *Brooklyn Eagle*.

Habitual good luck engenders carelessness; but there is no more striking example of the inconsistency of human nature than the fact that, while modern surgery demands the most scrupulous attention to details with regard to the preparation of the patient and the technique

of the operation, there has been no corresponding improvement in this country in respect to the administration of anæsthetics.

THE CURES OF MUCOUS ENTERITIS.

M. Germain Sée has so many cures for muco-membranous enteritis, that it seems impossible any one suffering from this usually intractable disease should fail to get well. First of all, M. Sée gives purgatives, and his purgatives comprise flaxseed, senna and hydrastis, castor-oil, and olive-oil. As to flaxseed, he tells us that the patient, immediately after each one of the three principal meals, should take a tablespoonful of pure flaxseed, placed for three or four minutes in a quarter of a glassful of cold water. If the flaxseed is objectionable to the patient, it can be substituted with psyllium. These substances are sufficient in themselves, in the majority of cases, to produce movements of the bowels, without having to resort to the administration of the various mineral waters, some of which, owing to the sulphate of sodium present in them, often give rise to constipation afterward.

Senna and hydrastis are given according to the following formula:

℞. Alcoholic extract of hydrastis canadensis..... gr. xxx.–xxxiv.
Senna leaves bathed in alcohol..... ʒ jss.
M. and make 50 pills. Sig.: 1 pill after each meal.

Every now and then other things are suspended and a dose of castor-oil is administered.

Olive-oil is given either by itself or in sugared tea, in doses of from three to four dessertspoonfuls the first day, morning and evening; the second day at noon, the same dose before the second meal; the third day, a glass at the same hours; and the fourth day, a whole glass at once. After this the patient must rest for four or five days—that is, the medication should be suspended, to be again renewed as prescribed. If the first trial shows a non-tolerance of the drug on the part of the patient, the method must be abandoned. Generally, however, the oil is well borne, more so than may be supposed, and "in these cases the muco-fecal movements produce an unexpected relief and sometimes a cure, at least for a considerable time."

Next, M. Sée gives sedatives, and usually in the form of bromides. But the bromides of calcium or strontium must be given, and not those of potassium or sodium, since the latter, he says, irritate the stomach. In our experience the others do so to just about the same degree.

Sée's formula is:

℞. Bromide of calcium,
Chloride of calcium.....āā ʒ ij.
Distilled water .....Oj.

In default of the bromides, he prescribes cannabis indica, as follows:

℞. Solution of gum arabic .... ʒ iv.
Extract of cannabis indica..... gr.ij.
M. Sig.: Three tablespoonfuls per day, one before each meal.

If great pain is present, one of the best modes of producing relief is the administration of menthol in the following manner:

℞. Menthol..... gr. ij.–iij.
Distilled water..... Oss.
Alcohol.....q. s. to dissolve the menthol.
M. Sig.: Two tablespoonfuls by the mouth t. i. d.

To diminish fermentation M. Sée knows of three efficacious means only by which to meet this indication, and he is in the habit of combining them. The first is the administration of the phosphate of sodium, which he places above any other antiputrefactive or absorbent substance. With from forty-five to sixty grains of phosphate of sodium a day he obtained "remarkable results." The amount of the drug is divided into three parts, each one of which is ordered to be taken in a little water, after meals.

For flatulence, the best remedies are salicylic acid in doses of three grains, and salicylate of sodium associated with six grains of the phosphate of sodium. These drugs will at the same time diminish the sensibility of the mucous membrane. Borate of sodium or borax is an excellent substitute for the agents mentioned, and it particularly aids the digestion of milk.

Yet, M. Sée's salicylic acid surely is irritating to the stomach, and despite all the remedies mentioned most cases of the disease, according to text books, do not get well. However, we present the views of a hopeful therapeutist, and trust they may prove useful to our readers.

NAVAL HOSPITALS.

So much interest surrounds the Government hospital care of the sailors when laid off from disease, but more particularly when disabled from injuries received in action, that we pick up with feelings of obligation to the author a brochure entitled "Notes on Naval Hospitals, Medical Schools, and Training Schools for Nurses," by Dr. J. D. Gatewood, Passed Assistant Surgeon, United States Navy. A sketch of hospital history prefaces a series of interesting accounts of these special hospitals in England and France, and then follow descriptions of the institutions at Portsmouth, Chelsea, Brooklyn, Philadelphia, Washington, Annapolis, Norfolk, Pensacola, Mare Island, and Yokohama, under the care of the medical department of the United States Navy.

In the absence of a complete treatise upon the subject these "Notes" are welcome, and aside from their value for the historical data contained, the plans which are given of nearly all the structures described make the architectural feature one to be consulted by those interested in such matters.

Smuggled Opium.—It is estimated by the Canadian authorities that at least 100,000 pounds of opium, refined in British Columbia, are annually smuggled into the United States.

Women Doctors in America.—According to a statistical report drawn up by M. Louis Frank, of Brussels, there were in 1893 on this side of the Atlantic fully 2,000 women practising medicine in one or other of its forms and inclusive of 130 homœpathists. The majority were ordinary practitioners, but among the remainder were 70 hospital physicians or surgeons; 95 professors in the schools; 610 specialists for the diseases of women; 70 alienists; 65 orthopedists; 40 oculists and aurists; and finally 30 electro-therapeutists. In Canada there is but one medical school exclusively devoted to the training of medical ladies, but in the United States in 1893 there were ten, one of them being a homœopathic establishment.

News of the Week.

The Plague Bacillus.—In *The Lancet* of August 11th is a short description, accompanied by illustrations of preparations made by Drs. Lowson, of Hong Kong, and Kitasato, of Japan, of the plague bacillus discovered by the latter. According to Dr. Lowson's description, the organism—which is a bacterium resembling the bacilli found in the hemorrhagic septicæmias, except that the ends are somewhat more rounded—when stained lightly appears almost like an encapsuled diplococcus, but when more deeply stained it has the appearance of an ovoid bacillus with a somewhat lighter centre, especially when not accurately focussed. When, however, it is focussed more accurately it is still possible to make out the diplococcus form. It is quite possible that the capsule has been produced artificially, though in one of the preparations shown this does not appear to be the case. The positions in which it is most frequently met with—sometimes apparently in almost pure cultures—are the glandular enlargements which occur in the groin, in the axilla, and in the neck, though these enlargements are not always met with in the rapidly fatal cases. These enlarged glands are intensely congested, or rather they appear to be infiltrated with blood. In this blood, which is in a state of disintegration, mixed with the elements of the glandular tissue which are also broken down, the organisms are exceedingly numerous. They are also met with in considerable numbers in the spleen and in the other organs, in those positions where there is a slowing of the circulation as it passes through capillary networks or sinuses, and are found even in the blood in the heart and larger vessels.

The British Medical Association in Montreal.—At the annual banquet of the Association, Dr. Osler, of Baltimore, speaking for the visitors, suggested that the Association meet in Montreal in the near future. All who attended would, he assured them, receive as hearty a welcome there as did the members of the British Association for the Advancement of Science a few years ago.

The Antitoxin Treatment of Diphtheria.—At a recent meeting of the Berlin Medical Society, Dr. Katz read a paper on the antitoxin treatment of diphtheria in the Kaiser Friedrich Children's Hospital. Since the opening of the hospital there had been treated by the usual methods 1,081 cases of the disease, with a mortality of 38.9 per cent. Since the middle of March of the present year 128 cases had been treated by antitoxin injections with a mortality of but 13.2 per cent. The doses of antitoxin employed varied from 5 to 20 grammes according to the severity of the case. No injurious effects of the drug upon the heart or kidneys were observed.

The Chinese Fire upon the Red Cross.—The London *Daily Telegraph* says that it is stated on high authority, that in the recent combats near Seoul the Chinese fired upon a Japanese ambulance carrying men who wore the Geneva cross. They killed a doctor and some hospital attendants.

Discontinuance of Examinations for the Medical Corps of the Army.—A recent act of Congress has reduced the number of assistant surgeons in the Army from 125 to 110. There are now 115 men in this grade, consequently there are no vacancies to be filled, and no examining board will be convened until the number is reduced by casualty or promotion below the limit mentioned. In the Navy, on the other hand, several vacancies exist in the Medical Corps, and there are not enough applicants to fill them. One reason for this is that assistant surgeons in this branch of the service, when first appointed, are messed with recent graduates of Annapolis, their juniors by several years in age and experience, and it is not until some time has passed that they are eligible for admission to the wardroom.

What Becomes of Old Diplomas?—An advertisement in a daily paper of recent date furnishes a partial solution of the problem as to what becomes of the diplomas of deceased physicians. The advertisement in question offered for sale the diploma of a physician who had recently died. The price asked was $50. The advertiser, when he learned that such a sale would be contrary to law, discreetly withdrew his offer, which he said he had made on behalf of the widow.

The German Imperial Family and Vaccination.—An anti-vaccination committee published a report that the German emperor had refused to allow his children to be vaccinated. After the report had started on its travel an inquiry was made, and it was found to be without any foundation in fact, for all the princes have been vaccinated just as any other children.

Sævitia Secandi.—Dr. O'Reilly, of St. Louis, recently appealed to the Board of Health of that city to exert its authority to prevent the wholesale mutilation of women at the hands of local surgeons. It was stated that many laparotomies were performed without the shadow of an excuse, and that these so-called surgical operations had but the semblance of legality in their performance to keep them out of the category of attempted or actual manslaughter. The *St. Louis Medical Review* admits that Dr. O'Reilly was justified in his appeal to the authorities, and that unnecessary operations on the abdominal and generative organs of women are scandalously frequent.

Anthrax in London.—During the past twenty years 118 cases of anthrax have been reported to the sanitary authorities in London. Of this number, 90 were in persons engaged in the hide and skin trade, 5 in persons engaged in slaughtering animals, 7 in persons engaged in the manipulation of horsehair or the manufacture of brushes, one was employed at a bacteriological laboratory, while in 15 instances the source of infection was not traceable. The number of cases among tanners shows a progressive decrease, due, it is said, to the fact that wet hides are taking the place of dry hides in the trade.

Dr. Cornelius Herz, of Panama Canal notoriety, who has been living in England since the trial of De Lesseps and others, has been condemned by default to imprisonment for five years, and to pay a fine of 3,000 francs. The sentence will be executed, if the French authorities can apprehend him.

Alcohol Free of Duty.—The Senate tariff bill admits free of duty alcohol to be used in the arts and for medicinal purposes. After its passage another bill was introduced in the House repealing this clause, but it has been shelved with the bills remitting the duty on sugar and raw materials.

Dengue has been epidemic at Key West, the disease appearing first among the troops and then spreading to residents of the island.

Not a Candidate for Congress.—The editor of this journal is not a candidate for Congress, as announced in various contemporaries. His name will not be mentioned in the convention which will be held on this date. The editor, however, cannot refrain from expressing his sincere thanks to those of his contemporaries who have kindly and favorably noticed his candidacy as announced in the secular press.—*Journal of the American Medical Association.*

The Woman's Hospital in Seoul.—In this hospital, the first of its kind in Corea, 2,765 patients were treated during 1893. Of this number 119 were hospital cases, 2,125 were seen at the dispensary, and 521 were visited at their homes. A large number of the outside visits were upon women of the wealthier classes, as it is not permissible for women of high rank to appear upon the street, although some of them do come in closed sedan-chairs to the hospital. The work has shown a steady increase during the three years that the hospital has been in existence. During 1891, in round numbers, 3,000 dispensary visits were made, 4,500 the next year, and 6,500 (representing 2,215 patients) in 1894, a total of upward of 14,000 visits.

Genius and Degeneration.—Dr. James Weir, Jr., writes that the sentence beginning, "Henry Clay was addicted to an over-indulgence in alcohol," in the article with this title in the MEDICAL RECORD for August 4th (p. 132), should read: "Daniel Webster was addicted to an over-indulgence in alcohol."

Sanitary Science in America.—Dr. de Pietra Santa, editor of the *Journal d'Hygiène*, says that among the United States, Michigan, Massachusetts, and Minnesota rank among the countries of the world in which sanitary science, both theoretical and practical, has made the greatest progress.

The Health of the Pope.—The cable reports that the Pope had an alarming attack of syncope on Sunday last, but that he is now in his usual health. His physician, in an interview with the correspondent of a Berlin paper, stated not long ago that the aged pontiff has no organic disease, and suffers only from the weakness incident to advanced age. His digestion is good and he sleeps like a child.

The Worm Turns.—Actions for malpraxis are so frequent that it is pleasant to hear occasionally that the tables are turned and the doctor is able to recover for slander. Dr. Thorne, an English medical man, has just been awarded damages for slander upon his professional skill by one of his patients. The defendant broke his collar-bone in the hunting-field, and the plaintiff was called in to attend him professionally. In consequence of some disagreement, Dr. Thorne gave up attendance, and advised his patient to go to another medical man. Soon afterward he found that the defendant's charges of malpraxis against him were being freely and publicly discussed, and brought suit for slander. A number of eminent surgeons gave evidence to the effect that Dr. Thorne's treatment was skilful and proper, and the jury awarded him £25 damages.

Treatment of Quinsy.—Dr. S. S. Cartwright writes that the treatment for tonsillitis, referred to by him in the issue of July 28th, was first proposed by Dr. A. S. Hudson, of Stockton, Cal., in an article in the MEDICAL RECORD of September 27, 1890.

The Thermogen is an appliance for keeping up the temperature of patients during an operation, doing away with the necessity of blankets and hot-water bags. It is in the form of a quilted cushion with an arrangement of fine wires inside by which any desired degree of temperature may be maintained by electricity. It was exhibited at the late meeting of the Royal Society in London.

A Life saving Appliance for Miners.—Dr. J. S. Haldane, of England, has invented an apparatus which, it is asserted, will enable miners to live from one to three hours in the after-damp which fills a coal mine after an explosion of fire-damp. The invention consists of a steel case, holding compressed oxygen and a respirator. The whole apparatus is no larger than a safety-lamp. It was shown by its inventor at the meeting of the British Association for the Advancement of Science in Oxford.

The Cholera persists in Eastern Europe, Southern France and Holland. The Czar has countermanded the orders for the holding of the army manœuvres at Smolensk owing to the prevalence of cholera in that vicinity. In Galicia, during the three days ending last Saturday, there were 237 new cases and 129 deaths, and in Bukowina, within the same time, 38 new cases and 21 deaths. The Austrian troops marching through this district to take part in the annual military manœuvres have assisted in spreading the disease. The Roumanian Government has established a military cordon on the frontier to prevent the introduction of the disease from Bessarabia, but as it cannot stop the flow of the infected river Pruth, it is difficult to see what good the cordon will do. Owing to the infection of the Vistula, and the consequent spread of cholera in the eastern provinces of Prussia, the orders for the army manœuvres in the neighborhood of Dantzig have been countermanded. In many of the towns in these provinces the authorities have closed the public baths and forbidden the use of unboiled water and raw fruit. A death from cholera was reported in Bordeaux on August 10th. The case was imported from Marseilles, where twenty-one deaths occurred during the fortnight ending August 17th. Cases are still reported in Amsterdam, Rotterdam, Maestricht, and other places in the Netherlands. A death is said to have taken place from cholera in Chelsea, in the southwestern part of London, and several cases were found among the crew of the steamer Balmore, which arrived off Gravesend from St. Petersburg, on August 7th.

"Intellectual California" is the title of a three volume report of all the congresses and other "intellectual events in California contemporaneous with the period of the Midwinter Fair." The Transactions of the 1894 meeting of the American Medical Association will appear in one of the volumes, which will be ornamented with the portraits of some three hundred of the handsome members of the Association. It is safe to assume that there will be some three hundred medical subscribers to the work.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-second Annual Meeting, held at Bristol, July 31 to August 4, 1894.

Special Report for the MEDICAL RECORD.

FOURTH DAY, FRIDAY, AUGUST 3D.

(Continued from page 218.)]

THE concluding general meeting was held on Friday morning, August 3d. There was a good attendance. THE PRESIDENT, who occupied the chair, introduced Sir Charles A. Cameron, F.R.C.S.I., in a few well-chosen and appropriate remarks.

Address in Public Medicine.—SIR CHARLES A. CAMERON, who was heartily received, then delivered the address in Public Medicine. He said they might claim that medical men stood pre-eminent among those who devised means for prolonging life and lessening sickness. They were the first to show that pure water was indispensable to health, that the efficient drainage of houses and of towns was a prime requisite to the maintenance of the health of communities, that overcrowding spread disease, if it did not develop it, and that the high mortality associated with many industrial occupations might be lessened by the adoption of certain precautions. The lives saved by the adoption of Jenner's sublime discovery of vaccination amounted to millions. In the government of modern communities the medical man played, even from a public health point of view, a very subordinate part, and yet there were many medical men eminently fitted, by their culture, experience, and ability, to hold the office of Minister of Public Health, aye, even with a seat in the cabinet!

Mortality rates in Town and Country.—In 1893 the mortality rate in the towns was 5.7 per 1,000 in excess of that in the rest of the country. The difference between the rural rate and that in some of the towns was appalling. Why had one British town twice as high a mortality as another, and why was the average duration of life so much greater in rural districts than in the towns? The causes were no doubt highly complex, and many of them were local. Among the poor in all towns birth and death-rates stood highest. Their greater fecundity and high marriage-rates compensated for their enormous mortality. The poorer a man was the more likely was he to marry. It was a remarkable but undeniable fact that a man's desire for matrimony was in the inverse proportion to his ability to maintain a family. Figures showed the appalling mortality of the children of the poor. If the deaths of children under five years of age were excluded, there would only be a difference of about 2 per 1,000 between the town and country death-rates. A large proportion of the lower classes in the towns was underfed, insufficiently clothed, and badly lodged. These unfavorable conditions told most severely upon the very young. As higher death-rates prevailed among the poor than obtained in the case of the well-to-do-classes, an undue proportion of very poor people in a town necessarily caused a higher death-rate than where the poor were comparatively few. This would be the case even where the general hygienic conditions of both towns were much alike. It might be considered that the comparative poverty of towns might be to some extent determined by ascertaining the proportion of the population who were domestic servants. On the whole, they found that in the towns where the domestic servants were very numerous the death-rates were low. The percentage of tenements which consisted each of a single room might, one would suppose, offer an indication of the poverty of a town. He found, however, the most extraordinary differences in towns, salubrious and otherwise, as regarded one-room tenements. In the Scotch towns one-roomed houses were even more common than in England.

In Dublin one-third of the families lived in single rooms. The high death-rate which characterized the denizens of single-room dwellings was largely the result of the miserable conditions of the people themselves, apart from the state of their dwellings. If they exchanged their one-roomed dwellings for four-room tenements, they would still have a high death-rate by reason of their poverty and its concomitant evils, and, he feared, from their intemperance. It was to be regretted that the local authorities still allowed such houses to be built. In Dublin they could not be erected, a by-law directly prohibiting their construction. In Dublin, 2,700 houses had been de-tenanted and closed—about 1,000 of them never to be reopened, without any compensation to the owners. If a municipality were wealthy it could do no better work than providing good dwellings for the artisans and laborers; but if its means were limited, it should look only to the wants of the laboring and still poorer classes. It was in the dwellings of the very lowest classes that the seeds of infective disease were nursed as if in a hotbed. These places were pest spots, and any amelioration of their condition must be a gain to society at large. The corporation of Dublin had been able to provide two-room tenements with separate sanitary accommodation of the most modern style, at 2s. per week, and without loss to the city treasury.

Water Supply.—The disuse of town wells and the filtration of public water-supplies had done much to lessen the urban mortality. The value of filtration through mere sand had until recently been under-estimated; but the researches of chemists and bacteriologists had shown that filtration through sand and gravel can be made almost as perfect as through charcoal. The great importance of water filtration was painfully demonstrated during the last epidemic of cholera at Hamburg. They had not yet determined, in relation to chemical analysis, the line which divided a bad from a good water, nor did he believe that such a line could be drawn. One that contained very little organic matter might be dangerous to drink, while, on the contrary, water with a large amount of organic matter had been drunk with impunity for years. The number of micro-organisms in water was regarded by most bacteriologists as a measure of its purity, regardless of its chemical composition. The epidemic of enteric fever in the Sees Valley in 1890 and 1891, investigated by Dr. Barry, of the Local Government Board, had been held to prove conclusively that this disease was propagated by water. Dr. Barry's conclusions had, of course, been questioned and controverted.

Sewer Air.—The results of recent investigations in reference to the composition of sewer air showed that it was superior, bacteriologically at least, to ordinary air. They could easily understand that in the case of well-constructed and constantly flushed sewers, the air in them would not differ from ordinary atmospheric air. It was the emanations from stagnant sewage in ill-kept sewers that were to be dreaded. The ventilating openings in the streets were generally objected to by those who lived opposite to them. Bristol was, perhaps, the only one of the large towns in which the sewers remained unventilated. As typhoid fever was asserted the most likely to be produced by sewer emanations, Bristol ought to have more than an average amount of disease, if the sewer ventilation theorists were correct. Statistics of the mean death-rate from enteric fever, in the period 1887 to 1891, showed that five towns had smaller rates than Bristol, and forty-four had higher. If Bristol had made a mistake in not ventilating its sewers, it had not apparently paid any penalty, for in the period 1881 to 1890 only one of the large towns had a lower zymotic death rate. He should feel disposed to adopt the Bristol plan, were it not that there might be some difficulty, in some towns at least, in cleansing the sewers. Typhoid fever was not so prevalent in these countries or on the continent as it formerly was, but in some towns typhoid fever had not declined, and in a few it had increased. There was a very general belief that this disease was

almost wholly propagated through the media of water, food, and sewer air; but he believed that the greater number of cases arose from the *materies morbi* of the disease being absorbed from the air. Up to the present, pathogenic micro organisms had not been frequently detected in the atmosphere, but neither had they been found, except rarely, in water or milk suspected to have produced disease. He believed that typhoid fever was a disease of the miasmatic class, and that it became endemic in certain localities in which the conditions of the soil were favorable to the development of the micro-organisms which caused the disease. It had been suggested that the waterlogged condition of Dublin was the cause of the prevalence of typhoid fever, and that the obvious remedy was subsoil drainage. It was, however, a fact that the low lying portion of Dublin, where there was most typhoid fever, was not damp, and that the ground-water lay low there, and that in the parts where the ground-water came much nearer to the surface there was least typhoid fever. The explanation of this was not difficult. The cold, wet clays were unfavorable to the bacillus of the disease, whereas they had better feeding-ground in the loose and well-aërated gravels. It was stated that typhoid prevailed most among the upper classes. This was not the case in Dublin.

The Future of Preventive Medicine.—The domain of public medicine was steadily enlarging in every direction. Surely the time must come when the results of these researches would enable man to extirpate some or all of the diseases which even now were termed "preventable." England had been described by foreigners as the birthplace and home of sanitary science, and it surely deserved the compliment. Never before in the history of the world were thirty millions of people located on fifty thousand square miles, as was the case with the England of to-day. Of these millions two-thirds resided in the towns, which yearly had a quarter of a million added to their teeming population. In Germany forty-two per cent. of the population lived in towns containing two thousand and upward. Only every tenth Russian lived in a town. Notwithstanding the great and continuous increase in its urban population, Great Britain grew healthier and healthier from decade to decade.

Professor Corfield, of London, moved that the thanks of the meeting be given to Sir Charles Alexander Cameron for his able and interesting address. It was due to Sir Charles that typhus had been so effectually grappled with in Dublin, for it was through his efforts that the insanitary dwellings which were the hotbeds of the disease had been swept away by hundreds. The same reason accounted for the failing power of the disease in Liverpool. At the same time there was the matter of the increase of diphtheria. Many causes were attributed to this, and among those which found most favor with the officials of the Local Government Board were the street ventilation of sewers, and the increased aggregation of children in schools. Alluding to the probable dispensing with vaccination, the speaker said that the opposition to this by the medical profession had been attributed to their desire to protect fees, but he prophesied that if vaccination became non compulsory the public would require half as many again medical practitioners as existed to-day.

Dr. Davies (the medical officer of health of Bristol) seconded the resolution, which was carried by acclamation.

The various formal votes of thanks having been given, the President of the Council (Dr. Ward Cousins,) moved a vote of thanks to the President (Dr. E. Long Fox) for his genial courtesy and marked ability in conducting the business of the congress.

Dr. Winterbotham, of Bridgewater, seconded the resolution, which was carried with great enthusiasm.

The President acknowledged this vote with a few courteous remarks.

A motion on the agenda in the name of Dr. T. G. Horder, of Cardiff, advocating an ethical section, was accepted for consideration in the name of the council.

A very cordial vote of thanks to Dr. Markham Skerritt, who had so well fulfilled the arduous duties of honorary secretary, terminated the proceedings.

SECTION OF SURGERY.

First Day, Wednesday, August 1st.

The proceedings of the section were opened by the President, Mr. Mitchell Banks, with a few remarks.

President's Address.—He said that no formal address was needed since Mr. Greig Smith would, on the following day, deliver the address on Surgery. Referring to the progress of modern surgery, he said that in studying the history of the art it was noticeable that those whose names were handed down to posterity were not the introducers or inventors of new methods, nor the brilliant operators, but the steady, practical observers who were content to have as their motto "Festina Lente." In studying of late years modern surgery and its tendencies, it had sometimes occurred to him that we might be going too fast, but he was happy to believe that this tendency, which a few years ago seemed to be strong, had lately been much modified, at any rate in Great Britain. It was our proud boast that the British surgeon, when he stood at the bedside, thought only of the sufferer as a patient, not as so much material for experiment. In surgery it was best to be sure that what was new was also true. Some politician had suggested that it would be an excellent thing for the country if no new laws were made for five years. He would similarly suggest that it would be a good thing for them if no new drugs or new operations were introduced for five years, so that they might study and thoroughly estimate the value of those that they have already. He believed that much time was wasted in the trial of old methods under new names, because they had not been thoroughly tried when originally introduced. He referred to the great harm done by the non publication of many unsuccessful cases, by which a false idea was conveyed of the merits of operations and modes of treatment. There were nowadays certain misguided sentimentalists who, in the lay press and elsewhere, abused modern surgery. These people were antivivisectionists and antivaccinationists, and when their views were a little more obscure and exalted—anarchists. The publicity given to surgical work and to hospitals, managed as they were by charitable and devoted laymen, was their best defence.

Operative Treatment of Perforating Ulcer of the Stomach and Intestines.—Mr. Pearce Gould then opened the discussion on this subject. He said that a good many years ago Dr. Marion Sims showed his keen foresight in prophesying that it would not be long before perforation of a gastric ulcer would be amenable to treatment by surgeons, and cease to be a hopeless condition. Eleven years ago, a distinguished Bristol surgeon (Mr. Nelson Dobson) read a paper in which he maintained that the proper treatment of this complication should be by abdominal section and suture of the opening in the stomach, or if it proved to be impossible to close the perforation, that a gastric fistula should be formed. The reception of these views was not a very encouraging one, but lately surgeons had more and more followed Mr. Dobson's advice.

In dealing with the subject, he would exclude all cases due to malignant disease and disease of the appendix vermiformis, and would first consider perforating ulcers of the stomach and duodenum.

The Pathology of the disease was mysterious. It occurred oftenest in anæmic young women, very often of the domestic-servant class, and less often in middle-aged men. He described the classical symptoms of gastric ulcer which, however, unfortunately formed no sure guide. They were sometimes entirely absent. Statistics showed that eighty-five per cent. of those in whom the existence of ulcer was diagnosed recovered. In 6½ per

cent. perforation and death occurred; five per cent. died from hemorrhage, and the remaining $3\frac{1}{2}$ per cent. died from exhaustion and other causes. Perforation occurred most often in ulcers of the anterior wall. Duodenal ulcers were most common in men. Billroth had recommended that as soon as ulcer was diagnosed a prophylactic excision should be performed, but the speaker did not recommend this treatment. Among other reasons against it were the facts that so many cases recovered spontaneously or under treatment, and that diagnosis was still very uncertain in regard to the position of the lesion, and some cases were so acute and perforation occurred so rapidly, that there was no opportunity of excision. When perforation was followed by escape of the contents of the viscus into the general peritoneal cavity, death sometimes occurred almost immediately from shock. In other cases shock might be almost entirely absent. The success of the operation, he believed, depended more on the complete and thorough cleansing of the peritoneal cavity—abdominal toilet—than on suture of the opening. He related several cases in illustration of this point.

Time of Operation.—The operation should be undertaken as soon as possible after reaction from shock set in, but it was better to wait till proper assistance and appliances needed for the abdominal toilet were at hand rather than to proceed without them. For flushing purposes he preferred boiled water containing one drachm of common salt to the pint (20 ʒ) to any chemical antiseptic solution. The solution should be of the temperature of from 110° to 112° F., and it exercised a marked restorative influence on the patient. Flushing should be done in a regular and systematic manner, and no time should be spared in making it thorough. It was the one essential step in the operation. He thought that excision of the ulcer was a needless and useless proceeding. In every case where peritonitis was well marked he made an incision above the pubes and drained the peritoneal cavity. When from the extent of the disease or size of the opening it was impossible to close it, the stomach should be drained. Seven cases were recorded of operation followed by recovery.

He cited seventeen cases of perforation from typhoid ulceration of the intestine which had been operated on. Of these one recovered. He excluded three cases of doubtful nature, all of which recovered. The ileum was the part affected in most cases, and there was often more than one perforation. It must be borne in mind that perforation sometimes occurred while cicatrization was in progress, and even months after the onset of the fever. Symptoms might be very marked or slight. Spontaneous recovery was very rare. Operative interference was only to be recommended when the fever had subsided or nearly so. With regard to ulcers of the posterior wall of the stomach which perforated, and sometimes caused subphrenic abscess, such abscesses should be opened and drained from behind if possible, or if opened in front a counter-opening should be made for drainage behind; this was almost essential.

Mr. R. Maclaren, of Carlisle, said that he had personal experience of four operations in such cases. Of these three were cases of gastric ulcer, of which two were fatal and one ended in recovery, and one case of typhoid ulcer which recovered, operation having been performed thirty-six hours after the perforation. Simple drainage without suture was all that was done.

Mr. Rutherford Morrison, of Newcastle, said he had operated on one case of gastric ulcer. There was peritonitis limited to the pelvis. The patient died, and at the necropsy it was found that the sutures held, the opening was securely closed. The perforation opened into the lesser sac of the peritoneum. He condemned excision of the ulcer.

Mr. Gilbert Barling, of Birmingham, gave details of several cases showing the difficulties of diagnosis and treatment. He thought that too optimistic a view was taken generally of these cases. Operations for the cure of perforating typhoid ulcers were of very doubtful expediency. If any operation were undertaken it should be as limited as possible. Opium he thought of great value in the treatment of the primary shock and after operation. Suture in typhoid ulcers was not to be advised.

Mr. Ward Cousins, of Southampton, spoke of the benefits of incision and drainage alone. It was remarkable how small a quantity of fluid escaped from the stomach in many cases. This was due no doubt partly to paresis, and hence the value of opium. He believed that flushing was a much more critical procedure than was generally thought. He would do it as sparingly as possible.

Mr. Haslan, of Birmingham, had operated on one case that ended fatally. He would draw a distinction between ulcer on the anterior wall of the stomach which caused general peritonitis, and ulcer of the posterior wall which often caused only localized inflammation. Unfortunately the classical symptoms of ulcer were more often present in the latter class of cases. Shock often came on as late as three or four hours after perforation. The difficulty of the operation was often increased by the rotation of the anterior surface of the stomach upward so as to hide the opening. Having once found the ulcer it was wise not to let it go again, as in his case much time was lost by neglect of this precaution. The edges of the ulcer should be inverted and Lembert's suture used. He would try to empty the viscus through the wound, but would not waste valuable time over it. He was an advocate of very free and prolonged flushing.

Mr. Nelson Dobson, of Bristol, said that although he advocated the operation eleven years ago, he had not had any opportunity of practising it. It was intensely interesting to him to find that his suggestion had been so generally adopted. He hoped, however, that too optimistic views would not prevail and cause the operation to fall into disrepute. He thought it almost futile to wait for shock to pass off. He would operate as soon as he was satisfied of the diagnosis.

Mr. Damer Harrisson, of Liverpool, generally agreed with previous speakers as regarded gastric ulcer. He doubted the occurrence of spontaneous recovery in cases of perforating typhoid ulcer. Diagnosis, especially in the acute stage of the fever, was often very difficult. He described one case in which two ulcers were sutured. Death ensued seventeen hours afterward, and it was found that the sutures still held. He would operate as soon as the diagnosis was made, and flush freely; hot water he believed relieved shock. In one case of typhoid fever in which perforation was supposed to have occurred there was distention and loss of the liver dulness. He opened the abdomen and found no perforation but a kink of the gut. The patient entirely recovered. He preferred to suture the opening in cases of typhoid ulceration.

Mr. Kendall Franks, of Dublin, had operated on one case with a fatal result. Much was to be learned from failures. He would always operate as soon as the primary shock had passed off, and would remove the diseased tissue and pass the sutures through healthy tissue. He thought that the occurrence of a second perforation in one of the cases cited by Mr. Pearce Gould was a silent witness to the truth of his view. Flushing was essential to success, but it was difficult to clear out the lesser omental cavity and the parts behind the liver and spleen.

Mr. R. O'Callaghan, of London, had operated unsuccessfully on two cases. He thought that no other condition in surgical practice showed such early and severe collapse. Early operation was imperative without waiting for reaction from shock. Opium was beneficial in case of shock, but not in collapse.

Mr. Pearce Gould said in reply that he was no advocate for delay, but he would not operate during primary shock when it was present (it was sometimes entirely absent). After the shock was rallied from, and before collapse set in, was the time for operation. As to the free excision advocated by Mr. Kendal Franks, he

said that it was all very well to sacrifice a few inches out of the twenty feet or so of intestine, but it was a more serious and difficult matter to remove a large portion of the stomach-wall and securely suture the remainder, whereas there was no risk of inversion of the edges causing trouble in the case of the stomach as it might in the intestine. As to the actual occurrence of spontaneous recovery from perforation of a typhoid ulcer it had been proved to occur sometimes by Cayley and Murchison's researches. We must beware that, in flushing, septic materials were not driven from the wound into the distant parts of the peritoneum and thus disseminated. Flushing should be begun at the periphery and ended at the wound.

The President in summing up the discussion said that the speakers seemed unanimous as to the question of suture. Washing out of the stomach was needless when the natural drain by the intestines was open. The question of spontaneous recovery was important. It appeared certain that in some cases it had occurred. Flushing seemed to be generally approved of, but of course it might be contraindicated by the patient's condition. Finally he must congratulate the speakers on the temperate manner of the discussion and the moderation of their views. He was glad to think that we were abandoning the ridiculously optimistic views common a few years ago in abdominal surgery.

Mammary Tumors.—Mr. Herbert Snow, of London, read a paper on the dispersal of certain forms of mammary tumor. These were the fibroma of adolescence, tumors due to inflammatory hyperplasia and certain tumors due to dilatation of ducts. The inunction of iodide of lead and mercury ointment four times a day would cause complete absorption of such in a few weeks, and so avoid the scars and other drawbacks of operation. He narrated several cases in point.

There was no discussion on this paper.

Traumatic Delirium Tremens.—Mr. Damer Harrison read a short paper on the treatment of traumatic delirium tremens. He referred to the method popular in Lancashire among colliers' wives to quiet uproariously drunken husbands. They would send out for two pennyworth of "Quietner" (three grains of tartar emetic) and administer it concealed in a pint of beer. He had adopted a somewhat similar treatment, which was really almost the same as the old treatment of fever. After morphine in full doses and chloral hydrate had failed of any effect whatever, tartar emetic, followed by chloral or morphine, produced complete cessation of the delirium, and after its use very small doses of narcotics took full effect. He quoted cases to illustrate this.

Surgery of the Gall-bladder.—Mr. Rutherford Morrison, of Newcastle, read a paper "On some Points in the Anatomy of the Right Hypochondriac Region, relating especially to Gall-stones." He demonstrated by diagrams and drawings the existence of a pouch of peritoneum behind the right lobe of the liver which was of importance in the surgery of the gall-bladder. It should be drained through the parietes immediately below the kidney.

Hernia in the Aged.—Mr. R O'Callaghan read a paper on the operation for strangulated hernia in octogenarians. He said that old people, especially old women, bore operation better than those in the prime of life. He described three cases which were all successful, although in two of them (inguinal hernia) the gut was almost gangrenous, and it was with great misgivings that he returned it, but he decided to do so because the boundary between the congested semigangrenous part and the healthy gut was ill defined, and after long douching with water at the temperature of 110° F. its appearance improved. He laid great stress on these points, as of great practical value. The treatment by enterotomy and the formation of a fistula was unsatisfactory and fatal. In case of gangrene enterectomy, suture, and return of the gut was the best treatment. He used no chemical antiseptics.

Hip-disease in the Aged.—Mr. T. P. Lowe, of Bath, read a paper on the treatment of senile rheumatic arthritis of the hip joint by forcible movements. He selected the hip joint as typical, and because in old people it was the first, and often the only, joint attacked. The symptoms were often mainly those of sciatica. Flexion was generally present, and was maintained by the presence of adhesions which should be broken through, an anæsthetic being given, if necessary, and in severe cases a Thomas's hip-splint should be applied. In mild cases the recovery was instantaneous and the patient could walk at once without pain. To break through the adhesions the patient should be laid prone and the thigh forcibly raised while the pelvis was held down. His experience led him unhesitatingly to affirm that synovial fluid could be restored to a joint which was dry.

Second Day, Thursday, August 2d.

Spinal Surgery.—Mr. W. Thorburn introduced the discussion on "The Surgical Treatment of Injuries of the Spine and Spinal Cord." To begin with, he would classify injuries, dividing them into eight classes as follows: 1, Unilateral dislocation; 2, bilateral dislocation without recoil of the displaced bone; 3, bilateral dislocation with recoil of the displaced bone; 4, fracture without recoil (diastasis); 5, fracture with recoil; 6, injury of lamina or processes; 7, compound fractures; 8, secondary lesions—hemorrhage, meningitis, etc.

After a careful survey and study of the subject his conclusions were that fracture-dislocation and dislocation were not difficult to reduce, but that the chances of recovery of the cord were not much improved thereby. A cord once crushed was incapable of recovery, as was shown by experiments as well as clinical experience. Any apparent recovery was due to vicarious conduction, some parts of the cord having escaped damage and being used instead of those normally employed.

The advantage of reduction simply was that a straight spine was better than a crooked one should the patient recover; but, on the other hand, reduction of dislocation in the cervical region was not without danger to life, and the more dangerous the higher up the injury. Reduction might be said to be safe and useful in unilateral and some bilateral dislocations. When the dorsal region was the site of injury reduction was not often possible.

As to laminectomy, in most cases of injury it was useless because when there was recoil of the bone the lumen of the canal was restored, and there was no pressure in at least two-thirds of the cases, and when there was no recoil, although laminectomy might be possible, yet there was not much hope of recovery, for nearly all the cases, even when there was recoil, ended fatally. When the continuity of tissue in the cord was once interrupted no restoration took place. He had found records of two hundred published cases and had personal experience of seven. In these seven he had seen no material benefit from laminectony in any case. Subsequent improvement was not due to the operation. In compound fractures (such as those caused by gunshot) he would remove fragments of lamina or other bone simply as a part of the wound toilet. When the laminæ were primarily injured operation was useful. There was no natural recoil and the cord was generally less crushed, and while the fragments of bone were usually small they might be doing harm by irritating and pressing on the cord. The gypsum corset was, no doubt, useful late in the case, but he was very doubtful whether it was of use immediately after the injury, while there was danger of the unseen formation of pressure sores and extensive sloughing.

Dr. H. L. Burrell, of Boston, U.S.A., said that he had a basis to go upon of 8 cases of laminectomy of his own and 4 of his colleague's, besides the collected records of 178 cases. The hopelessness of the condition when left to nature was well known and was demonstrated by him in a paper on the subject published in 1887. He then recommended that in all cases of dis-

location and fracture-dislocation an anæsthetic should be administered with as little delay as possible, for irreparable damage was done by allowing pressure to continue even for one hour. The patient should be suspended and forcible rectification practised, and a gypsum corset be applied. By the use of this method he had secured some brilliant results, but since the introduction of operation he had given it up for laminectomy. The do-nothing treatment should certainly be abandoned.

Immediate reduction had increased the recoveries by eleven per cent., and if such a blind method did so much good an operation that enabled the surgeon to see for himself the exact condition and remedy the displacement without doing more than needful must certainly do still more good. He doubted the possibility of an exact differential diagnosis, and therefore would operate on all cases.

Mr. C. B. Keetley mentioned a case in his own practice in which he applied a Sayre's jacket without attempting reduction. The patient entirely recovered. In another case of cervical fracture dislocation produced by diving from a height into a swimming-bath, an æsthesia and paralysis were complete in both arms and legs, but the right arm was somewhat contracted. He operated, removing the laminæ of the third and fourth cervical vertebræ. The lower margin of the fourth lamina nearly touched the fifth body. After removing the laminæ the cord seemed to return to its normal form, and there was afterward some return of power of movement, but the patient died on the fourth day. At the necropsy it was found that the cord was cleanly and completely divided but the dura mater was uninjured. He thought the operation in general was not a hopeless one, but that we should not be eager to operate. The risk of the operation itself was small. The dura mater need not be opened, and thus it was a little more dangerous to operate on a case of simple fracture dislocation than of compound. Still it must be admitted that the operation had its risks. He had operated on another case of fracture in the cervical region, but the patient died almost immediately. The necropsy showed fracture and hemorrhage at the base of the skull.

Mr. Gilbert Barling was quite in accord with Mr. Thorburn. We should beware of reckless operations which would only tend to bring laminectomy into contempt. A knowledge of the nature of the accident would often forbid operation, because we may often be sure from the extreme violence in indirect injury that the cord is divided or pulped, and in that case laminectomy was only "a crude way of administering euthanasia, in which we are not justified." He was quite sure that the operation had its own risks, and therefore it was wrong to employ it indiscriminately. He described two cases, one of direct violence to the side of the neck and arm—palsy, probably due to hemorrhage, ending in spontaneous recovery, and another of great indirect violence causing displacement of the twelfth dorsal spinous process and palsy of the bladder and lower limbs. Now two years after the accident there was complete recovery except for some patches of anæsthesia. This patient refused operation. This was one of the most hopeful cases for laminectomy, yet the operation would not have improved the result.

Mr. Barclay, of Bristol, thought that there was a tendency to be too cautious in these cases, but when there was a displacement of one vertebra from another, with recoil, operation was hopeless. When, however, there was no recoil and obvious displacement we ought to give the patient the chance afforded by laminectomy, and if necessary chisel away the projecting edge of the vertebral body which pressed on the cord. In cases of injury and displacement of a process or processes, if diagnosed, he would operate, but the diagnosis was often difficult. In cases where hemorrhage was diagnosed he would also operate.

Mr. Damer Harrisson said that in his opinion operation was rarely called for; those cases which he had wished to operate on and had been prevented had generally recovered. Fixation was the best treatment for fracture dislocation. He used a box splint, flexed the thighs, and drained the bladder, when it was palsied, by a perineal section, and was thus enabled to prevent decomposition of urine and cystitis.

Sir William Stokes, of Dublin, did not think that laminectomy alone could entirely relieve pressure, because the cord would still be stretched over the projecting body in front. He did not think removal of the projecting body possible without risk of increasing the injury to the cord; operation for direct injury was much more hopeful. He found that these patients did not bear fixation well, and there was great risk of sloughing under the gypsum jacket. He had never found any need of perineal section, but had succeeded in keeping the urine and bladder healthy by the use of boric-lotion injections.

Mr. Reginald Harrison detailed a case showing the benefit of immediate extension. He agreed with Mr. Thorburn and others as to the hopeless injury caused by indirect violence.

Surgeon-Major Hatch was not very sanguine about the operation. He had had five cases at the Jamsetjee Hospital in India; of these one was a case of injury to the cervical region and four of the dorsal region. In the first case there was meningitis present at the time of operation. No improvement followed. The patient died three months afterward. Necropsy showed that there was no pressure, and only slight narrowing of the lumen of the canal. Of the four cases of dorsal injury three died after laminectomy; in two the projecting vertebral body was gouged away without much difficulty and gypsum applied in the prone position; one of these died, the other improved after fourteen days, and was still improving. Of the other fatal cases, one was found after death to have an abscess on the canal below the lesion, the other died at the end of a week. He thought that reduction of the dislocation was not at all necessary. The difficulty of diagnosis was very great, and therefore he would operate to help the diagnosis, seeing that the prognosis was so bad. He did not think that secondary operations were hopeful. He believed there was a future before the operation.

Mr. Jordan Lloyd said that no one surgeon had a large personal experience of such cases. Fractures of the spine varied much in severity. Fixation gave good results. Cases of indirect violence were best left alone (except for fixation), and he would not consider operation in them. Cases of direct injury—generally in the dorsal region—were, however, amenable to operation. He had only operated on one case of recent fracture. The patient died. He would not operate on such a case to-day. He had, however, removed the laminæ of four or five vertebræ, eight years after the injury, for incontinence of urine and fæces, and the patient recovered control of them completely.

Mr. Noble Smith claimed to have benefited a case of fracture by the application of a spinal support pressing on the projecting bone. He had performed laminectomy in one case eight years after the accident. Improvement followed.

Mr. Thorburn, in replying, said that there seemed to be a general agreement as to the facts. There were at least two hundred cases recorded, and probably many less successful cases not recorded, hence, without waiting longer we were in a position to judge of the value of the operation. He could fully confirm what Surgeon-Major Hatch had said as to the feasibility of lateralizing the cord and gouging away the projecting body. A mistake in diagnosing the exact site of the injury was not important, it was easy to extend the incision and go further (generally higher).

Flat-foot.—Sir William Stokes read a paper on flat-foot and described Glück's operation of section of the os calcis and tendo Achillis in order to slide the bone downward and forward. He preferred to this and to

Ogston's operation a cuneiform osteotomy of the astragalus so as to replace that bone within von Meyer's triangle. He showed casts of a foot before and after operation.

Mr. Keetley preferred Ogston's operation, but in a severe case he had had to supplement it by osteotomy of the tibia and first metatarsal bone, thus producing a well-shaped foot; but he was bound to admit that the patient herself preferred the other foot, which was originally equally deformed, and had not been operated on. The pathology of this deformity was most complex.

Traumatic Gangrene.—Mr. Robert Jones, of Liverpool, read a paper on a case of acute spreading traumatic gangrene, treated by amputation and swabbing with pure liquefied carbolic acid. The patient was thirty-two years of age, and had a compound fracture of the forearm. The gangrene spread very rapidly, and at the time of amputation at the shoulder-joint there was swelling and crackling over the pectoral region and above the acromion. The soft parts cut through were dark, congested, and gaseous. There were practically no flaps. The wound and intermuscular spaces were freely swabbed with carbolic acid, and this was repeated at subsequent dressings. Recovery followed, hiccough night and day being the most distressing symptom.

Mr. Jordan Lloyd had a somewhat similar experience in two cases, aged thirteen and fourteen. After amputation he plugged the wounds with lint soaked in 1 to 1,000 sublimate solution and made some sixty inch or half inch incisions into the bronzed and brawny tissues above. Both patients did well.

Œsophageal Stricture.—Mr. Kendall Franks described a case of dysphagia from a stricture of the œsophagus just below the cricoid cartilage. At the operation (œsophagotomy) it proved to be due to a smooth double fold of mucous membrane completely closing the lumen, except for a slit like aperture (imperceptible from above) a quarter of an inch long. He excised the diaphragm and sutured the edges of the mucous membrane remaining. The external wound was closed around an œsophagus tube. The patient recovered. Such cases were rare, only nine were recorded since the seventeenth century. The pathology was obscure. The general opinion was that they were congenital, but in this case the patient (aged forty-six) had only had symptoms for three years. Could it be the result of prolonged spasm of the muscularis mucosæ and circular fibres? Mr. Franks also showed a drawing of a case of development of external piles into fibroid tumors after an operation for internal piles.

Third Day, Friday, August 3d.

Ovariotomy.—Mr. Mayo Robson read a paper "On a Consecutive Series of Ovariotomies performed in the Surgical Clinic at a General Hospital." He brought forward the details of 216 consecutive cases, without any selection, as evidence that the claim of obstetricians to have the monopoly of such cases was unfounded. General surgeons were the best fitted to succeed; they were prepared to deal with any complication that might arise. He had done 850 abdominal sections with a mortality of twelve per cent., including cases of suppurative peritonitis and one desperate case. Most of his experience was in the wards of a general hospital.

Of the 216 cases, 14 died. Of these two were cases of malignant disease, in two there was intestinal obstruction, one was admitted with peritonitis, in one a fecal fistula existed and the patient died eight weeks after the operation, one had a suppurating cyst, one died of bronchitis, caused possibly by ether (on this point he held strong opinions), one from heart disease, one was due to hemorrhage from slipping of ligature on pedicle of a sessile tumor caused by vomiting; one death was traceable to a collection of sewage under the ward. The mortality was six and a half per cent.

The risk of sepsis was put forward by obstetric physicians as an argument against the performance of ovariotomy by surgeons who were frequently dealing with septic wounds, etc.; but he submitted that the obstetrician who might have been attending cases of puerperal fever, and whose fingers were frequently in contact with vaginal and other secretions was more likely to convey infection. He thought further that for these reasons obstetricians ought to leave ovariotomy to surgeons. As to diagnosis, the surgeon who was familiar with various non-gynecological diseases of the abdomen was more likely to be accurate than the specialist. He was strongly in favor of the maintenance of the distinction between the physician and the surgeon. He emphatically protested against the pretensions of the obstetricians. If there was to be any specialty let it be that of abdominal surgery. If a surgeon is fit to operate on the kidney and the intestinal tract, surely he was fit to operate on the female organs of generation.

Mr. Ward Cousins warmly congratulated Mr. Robson on his cases. He thought that he scarcely did himself justice, however, by including so many complicated cases.

Mr. Nelson Dobson said that in Bristol ovarian tumors were operated on as a rule in the general wards, with results as good as those in special wards elsewhere. He had seen a case in which ovariotomy was undertaken by an obstetric physician, which proved to be one of tumor of the kidney; the mistake was entirely pardonable, but it involved the performance of an operation quite outside the operator's experience, and one he would not have undertaken had the condition been diagnosed.

Mr. Robson, in reply, said that he could fairly have separated his cases as Mr. Cousins has suggested, but he wished to give a table that could not possibly be cavilled at. If so arranged, his mortality would be only 1½ per cent. Uncomplicated cases were very rare in his experience, there were nearly always adhesions or other complications, such as twisted pedicle, which always gave rise to peritonitis. He used a temporary ligature before beginning to remove the cyst, when it was possible—thus lessening the bleeding in dividing adhesions. He could not agree with one speaker, who claimed that gynecology was all surgery and should be the surgeon's province. Many cases were medical, such as those of slight disease of the uterine appendages, which were best treated by medical means, such as rest, and it was most unjustifiable to operate on all these, for, apart from any risk of operation, it was certainly a disadvantage to a woman to lose her ovaries.

The President traced the origin of the pretensions of obstetricians from the days no operations were done on the abdominal cavity, and the treatment of ovarian tumor was medical. He protested against women's hospitals, officered by men in general practice, who had had no surgical training since their student days, and were not fit to suddenly plunge into capital operations any more than he (Mr. Banks) was to turn a fœtus in utero. He adverted to the recent inquiry at a women's hospital in London, which had involved the resignation of the staff.

Papers were also read by Mr. J. Hutchinson, Jr., on "Injuries of the Elbow-joint," and by Mr. Mansell Moullin on "Treatment of Enlargement of the Prostate by Removal of the Testes."

The passing of a cordial vote of thanks to the President, moved by Mr. Ward Cousins, closed the proceedings.

SECTION OF MEDICINE.

First Day, Wednesday, August 1st.

Dr. F. T. Roberts, as President of this section, opened it with a few remarks, in which he urged the necessity of broad views in medicine, deprecated the tendency to specialize, hoped this section would always maintain its position, and expressed his pride in being asked to preside over it this year.

Functional Diseases of the Heart.—Dr. Douglas

Powell said that though the term functional had been objected to, he rather favored it as useful to designate disorders which were independent of recognizable change of structure. In the case of the heart, the commonest causes of such changes were nervous strain, shock, acute specific diseases, and such like. The result is some impairment of the cardiac mechanism, when the pulse is affected in its frequency, tension, or rhythm. He deprecated the term tachycardia. Many of the cases so termed resembled angina pectoris. Others were more like Graves's disease. Pulse tension was most important, and the recurrent pulse often found with high tension ought to be carefully distinguished. Abnormal slowness, the so called "bradycardia," is found as a sequel of typhoid and influenza, and sudden changes from frequency to infrequency, or a normal rate with alternation to either, have been found. Subjective symptoms are usually well marked, the patients being often troubled with a consciousness of such symptoms as irregularity or intermittence. As to treatment, the causes of mental or physical over-strain must be removed. Then iron and arsenic are useful, and sometimes trinitrine may be called for. Dr. Powell illustrated his paper by the following tabular statement:

I.

Cardiac Vascular Hyperæsthesia.	Source of Altered Innervation.	Exciting Cause.	Method.	Rhythm
1. Undue perception of heart's action, normal or altered.	Central hereditary neurosis.	Mental shock, nervous exhaustion.	Variable degree of arterial tension.	Variable varicose tension.
2. Oppressed heart's action with raised arterial resistance.	Central.	Mental strain, nicotine constipation, uric acid, uræmia.	Regular, with arhythmic interludes.	Do.
3. Angina pectoris. *a*, Vena; *b*, Vera.	Cardiac plexus.	Mental emotion peripheral excitement, visceral.	V. M. excit. causing secondary cardiac embarrassment.	Slow, laboured, quick.

II

Heart's Action Accelerated.	Source of Altered Innervation.	Exciting Cause.	Method.	Rhythm.
1. Paroxysmal palpitation under mental excitement.	Central.	Intense volition in emergencies.	*a*, Shock; *b*, reaction: *c*, cardiac pressure: *d*, visceral relaxation.	Regular.
2. Paroxysmal palpitation from indirect vagus excitement.	Central.	Vagus inhibition.		Irregular.
3. Paroxysmal palpitation from direct vagus excitement.	Visceral irritation, strain, pericarditis, endocarditis, nerve strain, hot bath, mental shock.	Anæmia.		Irregular.
4. V. M. relaxation.				Variable.
5. Sustained hurry of heart.				Regular.

Dr. P. M. Chapman could not agree that all causes of functional derangements of the heart are of nervous origin, as irritability of muscle undoubtedly has a disturbing influence, and also fatty degeneration. Slowing of the pulse may be due to irritation of the vagus, and the best remedy is faradization of the vagus. Graves's disease is often looked upon as incurable, but he does not think so, as he has met with instances of complete cure. The manometer is indispensable to accurate diagnosis.

Dr. James A. Lindsay was of opinion that the symptoms of organic and functional heart derangements are often identical, but after excitement are more intense in the former than in the latter. The condition of the cavity walls affords conclusive evidence.

Dr. Ernest Sansom objected to the term "functional," and instanced amaurosis, which he defined as a disease in which the patient saw nothing and the doctor saw nothing. Similarly, in so called functional derangements of the heart, the patient often felt a great deal and the doctor could find nothing wrong. Acute pain might be present and yet the heart show no sign of disease or even trouble. "Fatty degeneration" of the heart was a huge bugbear; but people do not die of it suddenly; in his opinion it was more frequently associated with pernicious progressive anæmia than anything else.

Dr. G. A. Gibson had met with cases of cardiac affection where the pain was localized in the hands or the wrists, or in the forearms, and believed these pains to be due to some profound change in the heart itself, often proceeding from dilatation, and this was frequently referred to as proceeding from nervous disturbances.

Dr. Shingleton Smith said there was no test for cardiac neuritis, and functional could not be separated from organic disturbances; they were thoroughly mixed in such diseases as goitre, anæmia, and perhaps in phthisis. However, the difficulty of diagnosis should not be allowed to cause hesitation on the part of the medical man. He found nitrite of amyl act admirably in modifying the symptoms in cases of functional derangement.

Dr. Watson Williams found cactus grandiflorus a specific in these cases; and observed that even in health the arterial tension was subject to variations.

Dr. Harry Campbell agreed generally with Dr. Powell, but believes functional cardiac derangements to be the outcome of nervous disturbance, the result, as often as not, of heredity. Heart attacks often simulated epilepsy.

Dr. Mandford believed that many cases of functional derangement were due to vascular tension, and the effects of mental emotion were often identical with those due to fatty degeneration. In such cases mental, as contrasted with bodily, rest was of immense importance, and gave instances. Believed that even moderate doses of alcohol had the most mischievous effects.

Dr. Tyson said the slow heart of advanced age was due to organic lesions, and instanced the case of an old gentleman who always had what was supposed to be an epileptic fit when the pulse fell to 22. Attacks of "slow heart" were apt to come on in the night in elderly people who had partaken freely of supper, and were due to pressure by a loaded organ and the recumbent position. He advised food to be taken in the early rather than a latter part of the evening, a recommendation that was received with much applause.

Dr. James Barr said that the cardiac irregularities were evidenced by variations in the pulse, and that the right side was stronger than the left. He had seen the right auricle contract for four hours after the rest of the heart had ceased to beat. It was the stimulation of the blood that excited the action of the heart, and as the right side was the first to receive the vital fluid it was necessarily the stronger of the two; correspondingly, it was the first to suffer from overwok.

Dr. Rattray related his experience with the one word paraldehyde, which satisfied both the patient and the doctor.

Dr. F. T. Roberts, in summing up, said that he believed in purely functional derangements of the heart, and they caused much suffering when there was nothing wrong organically; he had frequently experienced it in persons, also in students coming up for examination. Tobacco was a fertile source of functional cardiac disturbance, and so was alcohol. Many doctors were quite satisfied when they detected a bruit, but he did not believe that an apical murmur signified much. He believed also that application of lanolin to the apical cardiac region would be vastly more beneficial than drugs in such cases.

Dr. Powell replied, and alluded to the incompressible pulse, which he did not deny; he thought that cardiac pain was an erroneous expression, as the heart itself felt no pain. He expressed his great satisfaction that the discussion on the functional diseases of the heart, which he had had the honor to open, had been characterized by so much interest on the part of those who had participated in it.

SECOND DAY, THURSDAY, AUGUST 2D.

Pyrexia and its Treatment.—DR. HALE WHITE opened the discussion, giving an able résumé of all that is at present known of pyrexia and the various means resorted to to combat it.

DR. DOUGLAS POWELL had seen in influenza a subnormal temperature quickly followed by a relapse, and this because the fall was due to nervous influences. Pyrexia, he thought, was as normal a feature of disease as the ordinary temperature of the body was of health, and he had thought he had seen harm result from lowering it below the standard of the disease.

DR. GARRETT-ANDERSON considered that temperature was comparatively unimportant, and instanced the case of relapsing fever. The temperature of children runs up very easily; also in the case of women, where there is more nervous susceptibility than in the case of men. The temperature of a child might run up to 101° F. and above it, without portending anything serious; the human body was not rigidly bound down to a temperature of 98.4° F. Then there was the high temperature of anæmia. Had known good results follow the raising of the head of the bed, and from the use of the Swiss bath.

DR. OSLER, of Baltimore, mentioned the high temperature of chorea, which was due to the increased muscular action; the more violent the muscular contractions, the higher the temperature, which he had known rise to 106° and 107°. Cases that present a low temperature at first may often rise to an abnormal height. Systematic cold bathing in typhoid fever was as much on account of the toxæmia that existed as on account of the pyrexia; was surprised this plan of treating pyrexia had not found greater favor than it had in the English-speaking communities of the world. The hydro therapeutic system of combating disease had certainly decreased the mortality. Did not believe that the use of the cold bath diminished the tendency to relapse.

DR. S. SMITH thought it was strange that after twenty-five years of trial it should still be necessary to discuss the question of the cold bath in the treatment of pyrexia; but the introduction into practice of various antipyretic medicaments has done away with its necessity, though there were cases in which nothing else would serve. He thought the bath might be dispensed with where the fever could be kept under by the use of antipyretics. He had never know any harm to result from administering a moderate dose of antipyrin every hour, and if this could be done the patient should not be subjected to the inconvenience and shock of being plunged into a cold bath; but where drugs failed the bath was necessary.

DR. M. SKERRITT rather liked the bath, and preferred quinine to any other of the antipyretic class of drugs, but in large doses, say from thirty to forty grains for an adult. The tendency to relapse was less frequent after the use of quinine than after the administration of drugs the action of which was more rapid. As long as there was breath in the body it was not too late to administer the cold bath; he instanced the case of a man who was actually moribund and recovered from typhus fever after being placed in a bath of cold water. Had also found it useful in cases of rheumatic fever.

DR. POPE queried whether a high temperature was not an advantage to the subject of a bacterial invasion, otherwise why should it have been perpetuated? The production of heat was due to increase of the heart's action, and antipyretics act by reducing that action. Found the injection of cold water into the rectum of great benefit.

DR. TYSON did not consider moving a patient, even when excessive pyrexia was present, to be injurious; far more harm was likely to result if the temperature had fallen below the normal. The high temperature so often met with in children readily disappeared after the administration of an aperient. He deprecated the practice of permitting young children to paddle in the sea, and believed it often was the cause of their temperature rising to an alarming height.

SIR T. GRAINGER STEWART thought no medical practitioner could be adverse to the cold bath; much depression followed the use of drugs. What was the best temperature for the antipyretic bath? 65° to 70° F. he found distressed patients, and would not advocate it except in severe cases; cold or tepid sponging was to be preferred, or the rapid changing of ice-cloths placed on the abdomen. The ice-pack, too, was of use. When he had recourse to the bath he used it warm, and gradually cooled it by the addition of cold water until the desired effect was produced; it was thus a less shock to the system than plunging the body at once into cold water. In rheumatism he had not found it so useful as in fever, but in pneumonia he had seen good results follow its use. He thought it very likely that climatic influences had a great deal to do with those varying results.

DR. OSLER thought the bath of primary importance, it had been carried out successfully at Montreal and Brisbane and all intermediate points. It was disagreeable to the patient and the doctor, and if a better plan could be devised he would abandon it, but as he saved many lives by its use he would continue to have recourse to it if it were to cause as much more inconvenience and trouble than it did; his only object was to save life.

DR. HERBERT SNOW was surprised that no one should have mentioned a well known antipyretic formerly much in vogue, namely, calomel; it acted, he thought, in a twofold manner, aperiently and antiseptically, by its conversion into bichloride of mercury.

DR. W. G. KEMP applied heat in the form of hot bottles to the feet when depression followed the administration of a cold bath. The lecturer had spoken of daily baths. He advocated one every four hours. The danger of moving the patient was readily obviated by attention. He thought doctors lost a great deal by not using aconite more freely, and recommended that the most prominent symptom should be first attacked, it was the disease. When antipyretics failed to produce their effect there was something beyond pyrexia in the background.

DR. HEATH favored antipyrin, had a case of pneumonia with a temperature of 106.1° in a lad of thirteen years, gave forty grains of antipyrin in ten-grain doses every hour, and saved the boy, his own son. Had found much advantage from the administration of creosote in the pyrexia and night sweats of phthisis. The sucking of ice was useful and agreeable to the patient, but cold baths were not applicable in private practice. He believed that the man who ordered them would soon find himself without any patients. He believed that the type of all diseases was much lower to day than a few years ago.

DR. GARRETT-ANDERSON said that the relation of idiosyncracy to pyrexia was too often overlooked.

DR. MAHOMED had no faith in antipyrin, he believed it killed a relative of his; has faith in quinine and ice-pack.

DR. BENTLY practised for fifteen years in the tropics, and gave quinine in malarial fever in combination with sulphate of magnesia. Alone, he found it had no effect. He found ice and packing of great use in cholera, even when there was collapse. In cases of influenza he used antipyrin and salycin combined.

DR. ROBERTS, in summing up, thought pyrexia was often due to unsuspected nerve lesions, and that removal could be effected with advantage in most cases except those of typhoid fever. He believed the possession of a clinical thermometer was not an unmixed blessing—to the doctor, yes; to the patient and the patient's friends, no.

DR. HALE WHITE, in replying, said he would gladly take away every clinical thermometer from the patients and their friends, who were often needlessly alarmed by its readings; ten minutes was long enough to keep a patient in the bath; a lowering of the temperature was not necessarily a sign of improvement.

THIRD DAY, FRIDAY, AUGUST 3D.

THE Section met earlier and for a shorter time this day and not so many were in attendance, and of these some were anxious to get away by an early train, and others to attend the concluding general meeting where the address in Public Medicine was to be given.

Ataxia.—DR. ORMEROD opened the discussion on this subject. He remarked that swaying about of the body when the eyes were closed was an indication of the existence of this disease; curious to say, a blind ataxic was affected in the same way when the eyes were shut. Ataxia was a symptom of disease in various parts of the body, but especially of cerebellar lesions, and less so of the cerebral hemispheres, the staggering was due to paralysis of the muscles of the back and legs. Disease of the corpora quadrigemina gave rise to a rolling gait. Disease of the spinal cord was not limited to any set of transverse fibres, but was most common where disease of the posterior part of column existed; it was a late symptom of locomotor ataxy. Motor weakness may exist in conjunction with ataxia. Toxic influences, expecially alcoholic, set up ataxia, also follow rheumatism and gout. Ataxia runs in families and is ranked with tabes, but he thought wrongly. Hereditary ataxia is of the cerebellar type, begins in the legs and works up. Friedreich's disease is hereditary affection of spinal cord.

DR. ROBERTS said he did not know much about ataxia, except, perhaps, as a subject for examination.

DR. ANDRIEZEN, of India, said forms of ataxia were due to alcoholism and to insanity, with a rapid breaking down of the brain tissue; also to tabes which involved the nerve cells in posterior tract.

DR. WALDO thought it was a symptom of brain, spinal cord, and peripheral nerve lesions, as well as of functional disturbances, as in hysteria. Walking backward was the surest test for ataxia.

DR. GORDON thought Dr. Ormerod's classification was pathological, and that a good clinical one was still a desideratum. The muscles were less paralyzed than not acting in unison, not backing each other up properly. In chorea the attempt at voluntary movement provoked involuntary movements of other muscles. Some thought it was a functional disease, but there was always hyperæmia, which had been said only to exist in cases that went on to a fatal termination.

DR. DAWSON WILLIAMS said that ataxia might follow any of the acute diseases, even malaria. This association of ataxia with acute diseases lent support to the syphilitic theory of tabes.

Hereditary Ataxia.—DR. MITCHELL CLARKE presented a patient, twenty-one years of age, suffering from Friedreich's disease. The following was the family history: Father's father died at eighty-three years of age, he was healthy; cause of death being old age. Father's mother died aged seventy-six, of apoplexy. Father's one brother committed suicide. Father's one sister died of heart disease. Mother's father living, aged seventy-two, healthy. Mother's mother died of heart disease. Mother's one brother healthy. Mother's two sisters died of diabetes within a few months of each other. Patient has one brother, aged seventeen, affected in same way; one sister, aged fourteen, strong and well. Three other children were still born, but no further evidence of syphilis in parents could be obtained. Patient himself has never had any bad illness. No other case in family; no cousins affected with nervous disease. From the age of eight till thirteen he was continually frightened by his parents' quarrelling. In both brothers symptoms are similar. The first symptoms noticed were the difficulty in standing and walking, especially in the dark, the peculiar gait and inco-ordination of movements. Onset about five years ago; probably early symptoms not noticed; in brother first came on about the age of twelve. Course slowly progressive, especially as to muscular power, but remissions occur.

A second case was that of a pale, pasty-faced man thirty-five years of age, fairly well nourished. He had lost the greater part of his hair. He never had any severe illness; has had gonorrhœa, but not syphilis. He never had fits, or any loss of consciousness. He is said, when aged five years, to have looked "silly"—that is, he could not stand still, rocked to and fro when standing, and kept his mouth open; he had frequent falls, and appeared to throw himself about when walking. He worked as an errand-boy till the age of twenty, when he had to leave off on account of falling frequently and dropping the things he carried. Since then he had been unable to work in consequence of growing clumsiness and weakness, the latter gradually increasing so much that he has become unable to stand without support.

The father of the patient, a butcher, suffered from heart disease and dropsy, and died in an asylum, apparently of melancholia. His parents died of old age, his father living to be ninety-six; one of his sisters committed suicide; family healthy. The mother is still living. Her father's father died at the age of ninety-nine, and her mother at the age of one hundred and one. Her father lost all his hair before he was thirty years old, and died of diabetes; her mother died at the climacteric period. There were two other sons and another daughter, all of whom survive. They had fourteen children: 1, Georgina, aged thirty-seven, healthy; 2, Albert, aged thirty-five (one of the patients); 3, George (drowned); 4, Isaac (died of croup); 5, a son, aged twenty five (examined and found healthy); 6, William, and 7, Mary Ann (both died at the age of five months, of "weakness"); 8, Lizzie, aged twenty one (examined and found healthy); 9, a daughter (died at the age of one month, overlaid); 10, Caroline, aged eighteen (one of the patients); 11, Isaac (died at the age of three years, of croup); 12, John, aged fourteen (examined and found healthy); 13, Isaac, aged eleven (one of the patients); 14, a child prematurely born at seven months (died in three days). The father was a heavy drinker; no evidence of syphilis could be obtained. The mother is a strong, healthy woman, and does hard work. Has never suffered from fits, from any nervous affection, or any severe illness. She was carefully examined as to state of reflexes, etc., and found to be normal in every respect.

Tabes Dorsalis.—DR. CLARKE then presented a third patient with locomotor ataxia.

Symptoms in 1892.—Chas. O——, aged fifty-three; weight, 12 stone 21 pounds; has had syphilis. Illness began two years ago with lightning pains in legs, difficulty in walking, numbness and loss of power in hands, girdle-pain, and giddiness increased in the dark.

March 2, 1889.—Ataxy, both of legs and arms, by far most marked in the latter; there is considerable weakness of leg muscles, with uncertain and high-stepping gait; movements of hands show great ataxy; he can only button his coat with difficulty and most clumsily; knee jerk present on the left side, just obtained on the right side. Right pupil does not react to light, left reacts only over one-third part of circumference on temporal side (no other sign of iritis). Paralysis of right external rectus; optic disks pale; both fields of vision irregularly contracted. Static ataxia and Romberg's symptom well marked. The metatarsal joint of right great toe is affected with a tabic arthropathy. Pains five years; difficulty in micturition two years. His state in February was as follows: No loss of sensation, gait extremely ataxic, inability to turn round and to stand with eyes shut and feet together; could not walk without a stick; myosis and inequality of pupils; Argyll-Robertson phenomena; loss of sexual power, knee-jerks absent, gastric and laryngeal crises; rectal pains, and lightning pains in legs of great severity nearly every day.

DR. ORMEROD, in reply, said he was glad those who had taken part in the discussion had in the main agreed with him.

DR. ROBERTS said that brought the meetings of the Section to a close. He thanked all for their good behavior, and said further that what he had looked forward to with dread had proved a pleasure.

New Instruments.

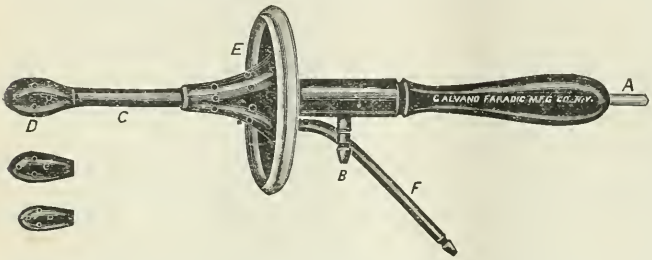
A NEW ELECTRODE FOR HYDRO ELECTRIC APPLICATIONS OF THE CONSTANT CURRENT.

By MARGARET A. CLEAVES, M.D.,

NEW YORK,

INSTRUCTOR IN ELECTRO-THERAPEUTICS, NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In the treatment of pelvic exudates, ovaritis, vaginitis, simple and specific, pruritus vulvæ, and eczema of the vulva, I have often felt the need of applying the constant current in such a manner that every part of the diseased tissue, of whatever nature, would be influenced by it. This is impossible with any electrode with which I am familiar. All of the electrodes for the application of the constant current in these conditions, whether metal or carbon balls wrapped with absorbent cotton, or clay and covered with gauze, I have found objectionable. In the first place, these electrodes can never be used but for one application without being re-made, otherwise there is danger of sepsis. Second, because of the very great danger, even in careful hands, of producing an eschar, a danger greatly intensified in the hands of the non-expert. Third, because of the impossibility of bringing every part of the diseased tissue under the influence of the current, or of utilizing the cataphoric property of the current in order to diffuse into the tissues such drugs as would be indicated, especially in diseases of the vulva and in vaginitis, simple and gonorrhœal. Some time since I adopted the plan of bringing masses of pelvic exudates under the influence of the negative pole by the use of the *Boudet de Paris* method. This method was originally intended to be used for constipation and intestinal obstruction. The bowel is distended, to the toleration of the patient, with salt water, which serves as the electrolyte, and to the electrode is attached the negative pole, the indifferent electrode (an Apostoli pad) being placed over the abdomen of the patient. It has been possible, in this way, to bring the exudative matter in the pelvis well under the influence of the constant current, and this without the slightest danger of producing a caustic action or untoward disturbance of any sort. Rectal applications, however, are open to serious objection, unless absolutely necessary. In casting about in my mind for a better method, the idea occurred to me of a vaginal electrode, constructed in such a way as to enable me to apply the constant current in the form of a douche, either negative or positive, and at the same time to carry out any indication for cataphoric medication, or the diffusion of medicated solutions into the diseased tissues.



The external part of the electrode, shown in the cut, is of hard rubber, the handle of which is filled in with a brass rod from the point of attaching the rheophore at *A*, up to the attachment of the hose of the fountain-syringe at *B*. From *B* to the end of the tube *C*, where the perforated cap, *D*, screws on, it is lined with a tube of carbon.

Brass, aluminum, and tin were all tried, but with the former only the negative pole could be used, with aluminum positive currents and diffusion of certain drugs was possible, but with even mild negative currents this metal was attacked. Block tin was too readily oxidized to make it advisable, and the expense of platinum and gold precluded their use; therefore, carbon was selected, and it bids fair to answer every purpose. The electrode must, of necessity, be straight, and cannot be curved as it could with a metal tube; this, however, seems to me of but little moment. The shield, *E*, is movable, and has two rows of perforations through which the surplus water drains into the tube, *F*. To this drainage-tube is affixed a few feet of rubber hose, of less diameter than that on the fountain syringe through which the water or the medicated solution gains egress into the vagina, in order to retard the drainage and keep the vagina distended during the time of administration of the current. This drainage hose is dropped into a jar at the foot of the operating-table, the syringe-hose is attached at *B*, the rheophore tip at *A*, and the vagina allowed to become well distended with the water or medicated solution, before the current is turned on. By firm and even pressure of the shield over the ostium vaginæ, with the labia folded out, so as to occasion no discomfort to the patient, it is possible to administer any quantity of the douche, one to three or more quarts, without getting a drop upon the patient's clothing.

I have arranged to have a cushion of soft rubber placed over the edge, as is done in ether inhalers, as will be seen in the cut. The suction action thus produced will render it possible at any time that full distention of the vagina is obtained, to maintain the same, by shutting off the drainage-tube by means of a clamp. The surplus water, however, that remains with continuous drainage is enough to penetrate every fold and rugæ of the vaginal mucous membrane, as I have demonstrated by cutting off the inflow and taking note of the amount remaining as it drained away.

The instrument is made with three different sizes of perforated caps, the smallest and largest with perforations at the side for vaginal use, while the medium sized cap not only has the perforations at the side, but at the end as well, and is to be used for rectal applications. To convert the instrument into a rectal electrode, the shield should be withdrawn. It will readily be seen that there is no point of contact of the conducting material of the electrode with the mucous membrane in either rectal or vaginal applications. The salt water or the medicated solution, whatever its nature, is the electrolyte. As I have intimated, this method of rectal application originated with M. Boudet, of Paris.

I have thus far used this douche-electrode in cases of pelvic exudates, chronic ovaritis, salpingitis, chronic vaginitis, and in chronic eczema of the vulva. In a case of chronic vaginitis and eczema of the vulva of twenty years' standing, with the most intolerable itching, for which the patient had resorted to various means for relief, and obtained none, I have found this electrode of the greatest value. In this case the entire mucous membrane of the inner aspect of the labia was thickened, leathery, and fissured. At the ostium urethræ and vaginæ the color was an intense crimson. The same condition extended into the vagina. There was extreme sensitiveness upon digital examination, and the patient was worn and harassed by the continued irritation from which she had not been free in all these years, despite the heroic measures that had been used to insure recovery. After one application of the negative galvanic current in the form of a douche, there was marked relief from the constant irritation and a tendency to heal on the part of the fissures. After four applications had been given, extending over a period of two weeks, the mucous membrane was found to be as sound and whole as that of a

child, and the congestion at the mouth of the vagina and urethra had entirely disappeared, the mucous membrane having returned to its normal color and condition. There was complete cessation of the itching which had made the patient's life wellnigh intolerable, and a most marked improvement manifest in her general appearance.

In making the application, the tendency is for the electrolyzed water to flow out against the shield, and in that way to come in contact with every part of the mucous membrane of the vulva. Patients find this method of applying the current exceedingly tolerable, and in the conditions for which I have used it thus far there has been an invariable expression of relief following its use.

It is my purpose, in having the electrode constructed of an unoxidizable medium, to use it not only for the application of the constant current, but also for the purposes of cataphoric medication. In gonorrhœal vaginitis—a condition which is recognized as extremely difficult to treat—it will be possible by this method to bring not only the os and cervix uteri, but every interstice of the vagina as well, under the influence of the medicated solution and thus combat the specific condition. The fact that the gonococcus penetrates the submucous structures, makes it very desirable that we should be able to apply our remedies in such a manner as to insure their destruction. By cataphoric medication this is possible, as the medicament not only comes in contact with the mucous membrane, but is caused to penetrate more or less deeply into its structure according to the strength of the current and the length of the application.

By means of anodal diffusion, a solution of sulphate of copper of requisite strength could be used to advantage in gonorrhœal cases. In the later stages of gonorrhœa, in conditions of pelvic congestion, uterine catarrh, and in some leucorrhœas, hydrastine thus diffused would be of much greater efficacy than in its ordinary administration by the mouth, or by means of vaginal injections. Bichloride of mercury in solution could also be used according to the indications and in strength of from one to one thousand.

That drugs thus used enter the local and ultimately the general circulation, no longer admits of doubt. This diffusion takes place, as a rule, from the positive to the negative pole, but in some instances from the negative to the positive.

In the treatment of syphilis, Gartner[1] and Ehrmann obtained not only the specific action of bichloride of mercury upon the disease, but ascertained its presence in the urine as well after from fifteen to twenty minutes' treatment with the galvanic bath, containing from four to six grammes of the drug. The positive pole was used and a current strength of 100 milliampères. These experiments have been corroborated by Kroneld in Professor Lang's clinic in Vienna.

In the treatment of gouty joints with bromide of lithium cataphoresis, lithium has also been found in the urine.

By means of the rectal electrode, if the conducting medium is of an unoxidizable material, cataphoric medication may be utilized to advantage in the treatment of chronic intestinal diseases, such as enteritis, simple, pseudo-membranous, or follicular; in intestinal catarrh, in fermentative and putrefactive conditions, and in chronic thickening of the mucous membrane of the intestines.

Once one is familiar with the properties of the electric current and the technique of the operation, the therapeutic applications suggest themselves in great abundance.

In all instances we are enabled to avail ourselves, not only of the electric diffusion of the drugs, but the physiological action of the current as well.

68 Madison Avenue, May 25, 1894.

Dr. John Williams, the accoucheur of the Duchess of York, is a Welshman who was formerly a general practitioner in Swansea.

A TYPHOID FEVER BED-BATH APPARATUS.

By RUSSELL BELLAMY, M.D.,

HOUSE PHYSICIAN, SECOND MEDICAL DIVISION BELLEVUE HOSPITAL, NEW YORK.

During the summer and autumn of 1893 many cases of typhoid fever were admitted to the wards of Bellevue Hospital, and in the different divisions many methods of treatment were employed.

Undoubtedly the method that yielded the best results was that of Brand; but, unfortunately, it cannot be extensively used in private practice on account of the great expense, often five nurses being required, two for night and two for day work, the fifth assisting at intervals. In hospitals this treatment can be used to much better advantage; but as now practised, and under the most favorable conditions, it has many drawbacks.

Having superintended and assisted in giving nearly twelve hundred baths I had an opportunity to note that the system must be changed in order to lower the mortality, lessen the expense, and cause the patient less mental agitation.

The method of giving a bath in Europe, and as used in this city by Peabody at the New York Hospital, and carried out extensively by W. Gilman Thompson at the Presbyterian Hospital, is used in the second medical division, under the supervision of visiting physician H. P. Loomis, and assistant visiting physician C. S. Quimby.

Present Method.—The patient, after being stripped and covered by a thin sheet, is lowered by three, and sometimes four, nurses into a bath tub and vigorously rubbed for fifteen or twenty minutes until the desired reduction in temperature is secured. He is then returned to bed, usually with considerable difficulty. If he is strong, the muscles are stiffened and the weight raised with ease. If the power of resistance is slight, as is usually found to be the case by the twelfth day of the disease, considerable difficulty is experienced in lifting him to the bed and sometimes a serious traumatism has occurred. At times the patients complain of pain over the region of the body where he is handled; again they complain of experiencing a tired feeling, and think the suddenness of being lowered into the water, or roughly raised, too great a shock and a rather heroic measure.

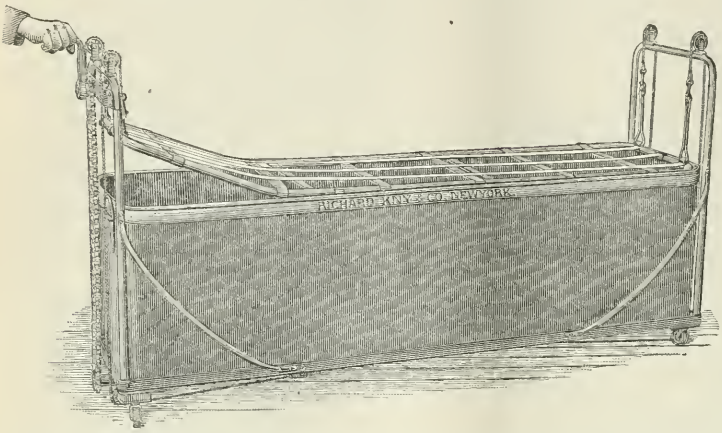
The close relationship between the visceral and parietal peritoneum to the abdominal muscles is to be considered, especially during the period of the disease when hemorrhage is most likely to occur, since at this time even a mild traumatism to these muscles could do much harm. I am inclined to believe that many hemorrhages and severe attacks of peritonitis will be avoided if the bath can be given without the least jar or exertion on the part of the patient.

After going over the literature of typhoid fever and consulting many of New York's most prominent physicians, I found that some different mechanism for giving baths is desirable.

The apparatus that Richard Kny & Co. of New York City, have so thoroughly constructed for me, consists of a galvanized iron bath-tub—one of any desired material may be substituted — 6 feet 4 inches long, 22 inches deep, and 20 inches wide. The supporting frame of this tub is on rubber wheels, and it is provided with a siphon exhaust-pipe, so that every drop of water can be removed in a few minutes. Supporting a comfortable steel mattress within the tub are four stout copper chains, passing over pulleys at either corner of the frame, and over a similar set under the tub. These chains are connected with an endless screw by cogs and a bicycle stop chain. The mechanism is controlled by a crank, so that the mattress can be raised or lowered by reversing the wheel. The apparatus is so arranged that the mattress can be raised several inches above the top of the tub, or lowered to the bottom. On one side a piece of galvanized iron, 2 feet long by 6 inches wide, is attached by hinges, and is used to bridge over the space between the tub and bed.

Method of Using.—The patient, naked, and covered

by a linen sheet, is placed upon a heavy rubber blanket, which is perforated near the centre; the bath tub is brought to the bedside, and the nurse, standing on the outer side of the tub and gently drawing the sheet, brings first the patient's head, then buttocks, and lastly feet, up on the steel mattress. A comfortable rubber pillow is placed under the head. The crank is reversed, the patient lowered into the water suddenly or by degrees, the bath given, the mattress raised to the level of the bed, and the water having escaped through the holes in the rubber blanket, the patient is transferred to the bed in the same manner that he was moved to the bath.



The steel mattress can be detached and the whole apparatus thoroughly disinfected. It is painted with white enamel and is not clumsy. In devising this typhoid bath-tub I had only hospital cases in view, and the manufacturer has so constructed this tub that it is adapted to the average hospital bed. Its height evidently can be modified as desired.

When we consider that a bath can be given by one attendant, and the patient experience no disturbance, either mental or physical, we feel that we have done something toward rendering the famous Brand system more generally available.

Large Increase of Lunacy in Great Britain.—The forty-eighth report of the British commissioners in lunacy, just issued as a Parliamentary paper, says there were in the kingdom, on January 1st, 92,067 lunatics, idiots, and persons of unsound mind, according to the various returns to the commissioners. This number is 2,245 in excess of the corresponding returns from the previous year, and shows the largest increase in the number of lunatics yet recorded. The report says: "This large increase calls the more for some special consideration, because it follows an increase of 1,974 in the preceding year, that being far above the average for the ten years 1882 to 1892, which was only 1,300. The increase seems to have been fairly general throughout England and Wales, but the predominant feature of the figures is the great increase shown in the county of London, its pauper lunatics numbering on January 1st, 800 more than they did a year previously. It is perhaps right in this connection to point out that from the administrative county of Middlesex, which is fast becoming metropolitan, there is shown from last year an excessive increase of 103, against an average for the previous ten years of 42. From one of the tables attached to the report it appears this state of affairs, though alarming, is not quite so serious when considered in conjunction with the increase of population, the ratio being one insane person in 326, as against one in 331 for the previous year."

Correspondence.

TRANSFER OF THE INSANE TO HOSPITALS.

To the Editor of the Medical Record.

Sir: In a recent number of the Medical Record the transfer of the insane from their homes to hospitals is discussed at some length, and the writer of the article criticises severely the system under which such transfers are made. His remarks are apparently intended to be general in their application so as to cover the entire country, but incidentally, and I have no doubt inadvertently, unwarranted strictures are made upon an important feature of the State Care Law, now in operation in the State of New York. The errors can be easily shown, and I trust the facts may receive the publicity they merit in the columns of the Medical Record.

That cruelties and inhuman practices were common a decade ago is only too true. Indeed the writer might easily have found much more horrible instances of brutality than those cited. The unfortunate victims of insanity were often treated like felons, and it was almost a daily occurrence that they were brought to hospitals in the strait-jacket, in manacles, or bound with ropes, and usually in a sad state of bodily uncleanliness. This terrible state of affairs was one of the strongest arguments used to secure the passage of chapter 126 of the Laws of 1890, familiarly known as the State Care Law. Section six of this chapter specifically made it the duty of the President of the State Commission in Lunacy "to prescribe regulations governing the transfer of public insane patients from their homes or from poor-houses to State hospitals by superintendents of the poor, and concerning the clothing of State patients." The President of the Commission accordingly, on September 10, 1890, issued the following order:

"1. That all county superintendents of the poor, or town, county, or city authorities, before sending a patient to any State hospital see that said patient is in a state of bodily cleanliness and provided with the following clothing, to wit:

"(*a*) One full suit of under-clothing. (*b*) One full suit of outer-clothing, including head-wear, boots, or shoes.

"Between the months of November and April, both inclusive, there shall be provided, in addition to the foregoing, a suitable overcoat for the men patients and a suitable shawl or cloak for the women patients; also gloves or mittens. Considering the great danger always present of the introduction of contagious or infectious diseases into institutions where large numbers of people are congregated, and to avoid so far as possible the introduction of such diseases by means of wearing apparel, the clothing above provided for must, in all cases, be new.

"2. In travelling by rail patients must not be compelled to ride in smoking or baggage cars, except in the case of men patients who may be so violent, profane, or obscene as to render their presence in ordinary passenger coaches offensive. If any portion of the route is necessary to be traversed by a team a covered conveyance should, unless impossible, be provided. The shortest practicable route should be selected; the hour of departure should be timed, so far as possible, so as to avoid

the necessity of stopping over night on the journey, and so as not to reach the hospital at any unseasonable hour. Whenever practicable, a notice in advance, by writing or telegraph, should be sent to the medical superintendent of the hospital of the coming of the patient. In cases of violent patients a sufficient number of attendants should be provided to control their actions without resorting to the use of mechanical restraints, such as straps, ropes, chains, handcuffs, etc.; quieting medicines should not be given to such patients except upon the prescription of a physician. If it becomes necessary to remain over night or for a number of hours at a station on the route, patients are not to be taken to jail, police station, or lock-up. Food in proper quantity and quality, and at intervals not exceeding five hours, should be provided for patients, but no alcoholic beverages must be given unless upon prescription of a physician. Opportunity must be afforded for attention to the calls of nature, and the rules of decency must be observed. In case of the employment of extra attendants in conveying violent patients, care must be taken that they are of adult age and of good moral character. The provisions of the statutes which require that a woman attendant shall accompany women patients when taken to State hospitals must be strictly complied with.

"3. Any violation of the requirements of this order shall be promptly reported, so far as known to him, by the Medical Superintendent of the hospital to the State Commission in Lunacy.

"4. This order shall take effect on the first day of October, 1890.

"By the President of the Commission,

"T. E. McGARR, *Secretary*."

The effect was immediate. The lot of the insane patient was greatly improved. Mechanical restraint, which had long been discarded in the hospitals, was thrown aside by county officials almost entirely, and the whole scheme of caring for the insane in New York State became more elevated in character in the letter as well as in the spirit.

The foregoing comprehensive order of the Commission continued in force for a period of three years, during which radical reforms were accomplished; but the best results were attained only when the State Care Act became wholly operative, October 1, 1893. On that date, under its provisions, the State Commission in Lunacy issued the following order: "The authorities of State hospitals for the insane shall send trained attendants to transfer insane patients from their homes or from poor-houses to State hospitals, as provided by section six of chapter 126 of the Laws of 1890. . . . Whenever possible, a few days' notice should be given to the hospital authorities of the transfer of the patient, and when the case is urgent the notice should be sent by telegraph or telephone."

It will, therefore, be observed that for nearly a year past the hospital authorities have regularly sent trained attendants to the homes of patients as soon as notice has been received that they have been examined and certified as insane, and have assumed entire charge of the cases at once. These attendants have been instructed to see that the orders of the Commission are fully complied with before starting for the hospital, and to provide for the patient every possible care and attention during the transfer, thus securing for him the protection of the hospital at the earliest possible moment. At the Binghamton State Hospital this plan has proved in the highest degree satisfactory. The attendants employed for this special work are competent, intelligent, and kind. They are thoroughly trained in the care of the insane, and invariably make their charges as comfortable as possible during transportation. When women patients are to be brought to the hospital, women attendants are always sent to bring them. Cared for in this way they usually come calmly and are much less disturbed or exhausted when they arrive at the hospital than was often the case under the old system. Besides attending to the patient's physical requirements our attendants succeed in obtaining good histories of the cases, and thus materially aid the physicians in deciding upon the proper course of treatment. All this is accomplished at a cost to the State rarely exceeding actual travelling expenses.

Surely the reform accomplished in the method of transporting the insane from their homes to hospitals in the State of New York, during a period of less than half a decade, merits stronger commendation than is to be found in the "undercurrent" which the editorial states is now running in the direction of reform.

CHARLES W. WAGNER,
Superintendent Binghamton State Hospital.
BINGHAMTON, N. Y., July 30, 1894.

THE INTRODUCTION OF LEPROSY INTO JAPAN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Beaven Rake, of Trinidad Leper Asylum, recently called my attention to the following passage, to be found in "Hirsch's Geographical and Historical Pathology" (translated from the second German edition by Charles Creighton, M.D.; London, the New Sydenham Society, 1885): "In Japan, according to the unanimous accounts of the chroniclers, it (leprosy) must have appeared as early as the thirteenth century B.C. (between 1234 and 1250)."

The authority for this statement is given in a footnote thus: "Schmid, New York MEDICAL RECORD, July, 1869, p. 194."

On referring to the MEDICAL RECORD of 1869, I find the following passage in "Notes from Japan," by H. Ernest Schmid, M.D., White Plains, N. Y.: "All records on that malady date its first appearance in Japan only as far back as from about 1234 to 1250."

As Schmid qualifies his statement with the adverb only, he evidently means A.D. and not B.C. Hirsch, therefore, seems to me to lean on a broken reed when he alleges the authority of Schmid.

There is no written evidence in Japan that leprosy was known there as early as the thirteenth century before Christ. But there is evidence that it existed before 1234 and 1250 A.D. Under no circumstances could Schmid mean B.C., there being absolutely no proof for such a date. It is believed that leprosy existed in Japan as early as the beginning of the eighth century, or even somewhat earlier. It may have existed there as early as it did in China, that is 1122 B.C.–314 B.C. But evidence to this fact there is none. There are written evidences in Chinese works of ancient treatments of leprosy which date back, one, 2,000 years, and the other falls between 618–690 A.D. Dr. Goto, now in Molokai, is authority for the statement that the disease was known in Japan in 718 A.D. According to Dr. Baelz, the Etas, the negro element of the Japanese Islands, are descendants of leper colonies; they are to day the leprous element of the outcast population. The origin of this negroid element is mythical; it does not fall in historical times; neither, as a consequence, does the origin of leprosy which this element represents. In this case the disease is supposed, naturally, by leprologists, to have come from Africa. In the Mongolian element of the Japanese it is natural to admit that it came from China, which would carry it back, at all events, to the epoch of the introduction of Buddhism from China and Corea, that is, to the sixth century. There can be no other reasonable theory as to the exact time when leprosy appeared in Japan.

Dr. Goto, of Honolulu, writes me, under date of July 8, 1894, that since February 8, 1885, to 1894, twenty-one thousand eight hundred and eighty-one Japanese men, and five thousand one hundred and ninety-one Japanese women, emigrated from Japan to the Hawaiian Islands. In this large number, five men developed the disease after their arrival, and four were suspected. This is quite the reverse of what happens at the introduction of Chinese emigrants. The Chinese seem to take the disease quite

naturally, and, indeed, it is they who are believed to have brought it originally into the Sandwich Islands. This also would be sufficient to warrant the suspicion that the disease in Japan came from the Chinese, as well as it did, if really it did, come through them to the Sandwich Islands.

Goto remarks that the Japanese made no change in their diet, and that fish remained prominent therein. We may remark in passing, that if fish diet was a factor in the transmission of contagion, there would have been more of an outbreak in such a large number of Japanese in nine years (one person a year).

Dr. Basadre, of Lima, Peru, informs me that the only cases he has observed in Peru were always Chinese, never Peruvians.

Dr. Muñiz says that leprosy is very rare in Peru, and that only a few (Chinese) are affected by it. In 1893 there were only two deaths from leprosy, and at the time when Dr. Muñiz wrote to me, there was only one case at the Hospital del Refugio, and it was a Chinaman.

Hence we may assume confidently that to Japan, the Sandwich Islands, and to South America, leprosy came from China.

ALBERT S. ASHMEAD, M.D.

45 MACDOUGAL STREET, NEW YORK.

CYANIDE OR FERROCYANIDE OF POTASSIUM?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: One word about the cyanide of potassium poisoning case mentioned in the MEDICAL RECORD of July 7th. It is evident that some drug was taken, but it could not have been cyanide of potassium. The patient says: "I took a solid piece, perfectly smooth on all sides;" this fact alone is conclusive, for cyanide of potassium does not occur in that form, but ferrocyanide of potassium does, hence it must have been the latter drug. It appears that the doctor did not see the drug himself, which renders the case doubtful. Cyanide of potassium is one of the most formidable poisons known to chemists. It has destroyed life in a quarter of an hour, and tetanic spasms occur in a few seconds or minutes, and run through their course with great rapidity.

J. H. TRENT, M.D.

BROOKLYN, N. Y.

DOSIMETRIC MEDICATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Being one who is a believer in the dosimetric method of administering medicines, I have read Dr. Mann's article on "A New Cardiac Tonic Dosimetric Granule" with much interest. With the general purport of that article I am thoroughly in accord; but I regard it as unfortunate that Dr. Mann uses the term dosimetric, as his granule is not in reality a dosimetric granule at all. On the contrary, its composition contravenes three of the fundamental principles of dosimetry:

1. Dosimetric granules contain one medicinal principle only in each granule.

2. They contain a fixed, usually minute, amount of the drug. That is to say, for instance, the morphine granule always contains one milligramme, the strychnine granule one-half milligramme, and so on.

3. They are made according to the metric system.

It is in the first two of these principles that the strength of dosimetry lies. The physician adjusts his treatment to each particular case, giving so many of one kind of granule and so many of another, and can vary the proportion from time to time, whereas if relying on a number of ready-made prescriptions like Dr. Mann's, he will inevitably in many cases give, not what would be the best prescription for the patient, but the nearest he happens to have at hand, in his case or office. To my mind nothing tends so much at the present time to hinder the progress of scientific therapeutics as the slovenly habit, which is so wide spread, of using ready-made formulæ, mainly in the form of tablet triturates. Dosimetry aims among other things at the abolition of this habit.

Perhaps it is hardly necessary to add that Dr. Mann's prescription can be represented approximately by the dosimetric granules already in use, thus:

Morphine hydrochlorate....	5 granules (5 milligrammes).
Strychnine sulphate.....	1 granule (½ milligramme).
Atropine.....	1 granule (¼ milligramme).
Caffeine.....	1 granule (1 milligramme).

Contagious Diseases — Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 18, 1894.

	Cases.	Deaths.
Tuberculosis	111	98
Typhoid fever	26	10
Scarlet fever	28	6
Cerebro-spinal meningitis	0	6
Measles	31	1
Diphtheria	122	27
Small-pox	3	0

A Pasteur Institute has been opened in Tunis.

The Monument to Surgeon Parke, the medical officer of the Emin Pacha relief expedition, which is to be erected in Dublin, will represent him in the dress worn in Africa during the expedition, standing with crossed arms leaning on a gun, resting the left foot upon a medicine chest.

Nasal Reflexes.—For the diagnosis of "nasal reflex neurosis" Zarniko requires, 1, that every other possible explanation should be eliminated; 2, that there should be present some local reflex symptoms (for example, fits of sneezing), such as are known by experience to be frequently associated with remote nasal reflex neuroses; 3, that the inspection of the nose should reveal such changes as frequently set up reflex disturbances; 4, that artificial irritation (probing) of some area in the nose should excite the reflex symptoms; and 5, that anæsthetization of that area should put an end to them. In some cases he considers the last two points sufficient ground for the diagnosis.—*British Medical Journal.*

The Value of Our Mistakes.—It is always a pleasant thing to be right, but it is generally a much more useful thing to be wrong. If you are right, all that you do, as a rule, is to confirm your previous opinion, your previous habits of reasoning, and your previous self esteem. But if you are wrong you generally gain in knowledge and gain perception of the way in which your method of diagnosis needs improvement, and the influence on self-esteem is not likely to do you harm. At least that is my own experience, and I think I have observed it confirmed in others. But the result is dependent on deliberate effort. There is a strong temptation to smooth down error, and it is very easy not to gain from it its precious lesson. It is more easy to fancy that there is some accidental cause for the mistake than frankly to perceive that it is a fault. But if you make a deliberate effort to realize and to face in your own mind the mistake you have made, to discern its cause, and to employ this perception as far as you can to remove the cause and prevent a like mistake in the future—if you do this, almost every error becomes one of the precious experiences of your practical life.—DR. W. R. GOWERS.

SEWER GAS A CAUSE OF THROAT DISEASE; OR THE EFFECT OF BAD DRAINAGE ON THE THROAT.[1]

BY BEVERLEY ROBINSON, M.D.,

CLINICAL PROFESSOR OF MEDICINE AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

"A GREAT deal of vague assertion has been made with regard to the effects of sewer gas, or as it is better called, sewer air, upon the human system. While some look upon it as always poisonous, and often virulent, others consider it usually harmless, though unpleasant. The good health of workmen engaged constantly upon sewers is cited in favor of this latter view."[2]

The opinion just quoted manifestly shows that there is much of expressed opinion on this subject found in medical literature which is based upon facts capable of widely different interpretation. In a tenement house, let one or more cases of throat disease be suddenly present, and the attending physician immediately suspects the condition of the plumbing. A sanitary inspector from the Health Board is called. Untrapped, filthy sinks, malodorous water-closets, a damp cellar containing accumulations of organic substances, animal or vegetable, in a state of decomposition and giving off effluvia, will usually be discovered. Not infrequently, in addition to these sources of disease, the peppermint or smoke test properly applied will make known a leaky joint, or a perforation of the soil-pipe, which allows sewer air to permeate the entire building. Which of these conditions —or do all combined—occasions the throat affections which have shown a sudden outbreak, or been present more or less continuously? How difficult to decide in a satisfactory manner!

Whenever, besides the preceding conditions, we find overcrowding, poor ventilation, bad food, lack of personal cleanliness, over-fatigue, exposure, anxieties, poverty, excesses—how can we properly estimate the *rôle* of each determining or causative factor of the throat disease in its exact proportion? Evidently in many instances the task is very difficult, not to say insuperable. And yet there are unquestionably numerous examples on record in which the impure air from sewers and cesspools has seemingly been the means of propagating diphtheria and other throat diseases. Instances, indeed, are not wanting which go to show that the poisonous decomposition of organic matter in sewers is in some way connected with the dissemination of these diseases.

Dr. Chaumont publishes two cases in support of this opinion. One is that in which a number of children were attacked with diphtheria, apparently caused by a leakage of sewage in a part of the house immediately under the nurseries of the children. The other case was that in which by a defect in the sewer-ventilating pipe passing up close to the cupboard in a nursery, there was an escape of sewer-air into the room occupied by a number of children, with the effect of sickening the whole of them.

Dr. Wilson[3] remarks that "in country districts isolated outbreaks of diphtheria traceable to cesspool effluvia are not at all uncommon. In these cases it is generally found that there is a water-closet in the house which itself is badly ventilated, and that the closet drainage discharges into a cesspool which is completely covered up and only cleaned out at rare intervals. The consequence is that any gases generated in the cesspool have no outlet except through the water closet and into the house, and hence result attacks of diphtheria, ulcerated sore throat, and other badly defined ailments."

"From an inquiry instituted by the State Board of Health of Massachusetts in 1875, respecting the predisposing causes of diphtheria, its prevalence, etc., it would appear that this disease has been most severe in the rural districts where there are no sewers and where the drainage is generally very bad. In some of these places the level of the ground-water is high, and on this account when there is high water many cellars are damp or contain standing water. This is probably one of the worst sanitary conditions in connection with diphtheria. It helps perpetuate it by furnishing a breeding place for its disease germs if they become implanted, and it also favors catarrhs and sore throats, which render persons having them more susceptible to that disease. Besides the conditions referred to, the soil is often polluted from house slops and excavated privy-pits."[4]

"The belief that the propagation of diphtheria is greatly influenced by contaminated air from sewers, privies, soils, etc., or, in other words, by filth infection, seems to be gradually gaining ground; but at present evidence is not sufficient to justify a decided opinion."[2]

"Perhaps these faulty conditions produce a sore throat of a benign character which affords a soil suitable for inoculation by the diphtheria germ when present in the air."[3]

According to other writers, defective sewerage, dampness, and lack of cleanliness, account undoubtedly for most cases of diphtheria developed in private houses.[4] Indeed in some of these instances the presence of the Loeffler bacillus, the true cause of diphtheria, has been shown in the gases arising from sinks.[5] We owe this demonstration to the researches of Dr. Fischer, who has shown also that these sinks are not properly flushed, and that for this reason they often become the breeding-place for these and other bacteria. In commenting upon Dr. Fischer's researches Koehler states that the portion of the waste pipe of washstands and sinks between the outer opening and the first trap is particularly objectionable for this reason. This portion of the pipe receives varying amounts of organic matter and water, which is exposed to and warmed by the air of the adjoining room. These are, of course, suitable conditions to produce an excellent culture ground for many kinds of micro organisms. The traps of a house may, therefore, be in perfect order, and yet we may not be safe from infectious sore throats. The condition just referred to is usual, and yet frequently cooks and others escape sore throats, at least for a time. When they are otherwise well, the chances are that they will escape; when they are ailing for one reason or another, they are more likely to contract a sore throat from habitual contact with the source of contagion mentioned.

Many people, both adults and children, before con-

[4] MEDICAL RECORD, September 30, 1893, p. 422.
[5] Ibid., January 28, 1893.

tracting diphtheria or other affections of the throat have been weak or sickly. The vitality of their body-cells is already lowered, and they are thus rendered more susceptible to the action of virulent germs. Many agencies conspire to bring about this condition; such are, notably, wet and cold, hunger, physical or mental depression, worry, and severe shock. In many instances diphtheria, follicular tonsillitis, and other forms of sore throat have been known to follow exposure to some of these causes, and independently, as far as can be known, of any infection from dirty pipes.

It is an admitted fact that the throat swarms with bacteria at all times, and possibly the Loeffler bacillus is among them occasionally,[1] but they are incapable of doing much harm to the individual carrying them if he be in good health. Through the depressing influences referred to they are capable of multiplying and increasing in virulence, and finally causing infectious sore throats. The sore throat may be taken indeed by the individual who first receives or develops the bacillus, or he may infect other persons without himself having given evidence of sore throat or other disease.

From what precedes, we should see clearly how important it is to keep up an excellent condition of general health in order to avoid contracting throat diseases. It is also evident that proper disinfecting washes or gargles for the mouth and throat are very important to keep it in a condition where infective bacteria will not develop, or, if present, will not take on virulent properties. These precautionary measures, which are or may be useful at all times, and particularly for children, are likewise specially desirable for the delicate ones, and in times of epidemic or exposure in any way to the sources or causes of infectious sore throats.

The aggravating effects upon the condition of the throat of effluvia from sewers and drains is, then, most probable. While the distinct connection between the two conditions cannot always be determined, yet in very many cases it is clearly demonstrated. Moreover, reasoning by analogy it should be true, inasmuch as sewage emanations are known to aggravate the severity of all the exanthemata, erysipelas, hospital gangrene, and puerperal fever (Rigby); and it would seem that all diseases are more or less affected by these effluvia.[2]

That many cases of tonsillitis are immediately caused by the air of sewers and fecal emanations scarcely admits of reasonable doubt. The evidence in this direction is very convincing, and I am persuaded that I have seen these affections dependent to a great extent upon the polluted air of sewers, cesspools, and of the soil. We can properly explain the throat affection, it seems to me, in the same way we do the development of typhoid fever. "The morbific agent conveyed through the medium of the air finds its way into the houses from cesspools improperly located, or from drain pipes imperfectly ventilated or badly trapped, or from impure soil beneath and surrounding the dwellings. With the doctrine that the disease is not in the micro-organism itself, but in its products, we may have floating matter which is not living and yet which is infective; so the gases of certain kinds of decomposition may be sources of contagion without our deciding whether or not they have been produced through the agency of low forms of life.[3]

"In some cases sore throats have been confined to a particular part of the house, especially exposed to the effluvia from badly trapped drains; and as the water supply was unexceptional, and other sources of disease could not be found, there could be no doubt as to the source of the infection."

[1] That Loeffler bacilli are present at times in considerable number in the mucous secretions of the tonsils and pharynx of children apparently in good health is now clearly established. This important and suggestive fact we owe to the researches of Drs. Chappell and Park. Vide MEDICAL RECORD, April 14, 1894.

[2] Buck: Hygiene and Public Health, vol. i, p. 585; quoted from Parkes.

[3] Report of the Board of Health of the State of New Jersey, 1893, p. 76.

Even though we might be inclined to give a different interpretation to some facts of an analogous kind, yet what we can say is that in many instances in which the bad sewerage has been partially, or more or less thoroughly remedied, the throat affections have notably lessened, or disappeared almost entirely for a while. In this direction we have the unbiassed and careful testimony of many judicious observers. Thus Dr. Billington, of New York, writes in regard to the etiology of diphtheria: "The relation of cause to effect has been demonstrated by the fact that in some buildings which had come to be looked upon by me as diphtheria nests, there has been no recurrence of the disease for quite a number of years since the evils referred to, viz., foul cellars, neglected cesspools, bad plumbing, untrapped sinks, no air-shafts, were removed through the efforts of the Board of Health. It is probable, moreover, that it is, in some degree at least, a result of the removal of these foci of the disease that the mortality from diphtheria in the ward of which Dr. Billington was an out-door visiting physician, has become very much less.[1] The experience of Billington is corroborated by that of others. Thus "the persistent attacks of enteric fever (and also diphtheria?) which formerly occurred at Eastney Barracks in England were due to sewer-air being forced back by the tide, no traps or ventilating openings being supplied; since this was remedied and ventilation carried out, no case of fever has occurred." [2]

On the other hand, I have known diphtheria and follicular tonsillitis to occur, and not infrequently, in houses where the closest investigation could show no defect whatever in the sewerage of the house, where the cellar was clean and dry, where ventilation was excellent, and where, indeed, no discoverable and satisfactory cause of the kind referred to could account for the development of these diseases. At first thought this fact would appear to support those observers who claim that insanitary conditions, due especially to defective plumbing and drainage, have very little to do in occasioning an outbreak of throat disease. This statement I can only admit in so far as to say that imperfect sewerage is only one of the efficient causes of diphtheria and other throat diseases, and that numerous other causes of these affections may and do exist. These other causes, already referred to, are especially active, no doubt, in times of epidemics. In cases of diphtheria and other throat diseases due to endemic causes, it is quite clear at times that the bad sewerage of the house acts in one of two ways: First, in causing a condition of the throat upon which the specific bacillus of diphtheria, or other micro organism, can graft itself more readily; second, in developing, perpetuating, or perhaps in originating, the specific bacillus or other microbe which is frequently present in the air of a certain house or locality.

Again, in estimating the influence of drainage in producing throat disease in certain houses of the rich, and even though no visible defect can always be discovered, it must be remembered that in view of the complicated and multiform appliances of modern plumbing, they "have seemed to multiply rather than to obviate the insidious dangers from noxious miasms." [3]

Be it observed, also, that American houses, as a rule, have no other way of changing the air than by opening the windows. Water-closets oftentimes are found with no connection with the outer air, located in the middle of the house, and what ventilation there is, is into the rooms of the house.[4]

According to Jacobi [5] cases of diphtheria which are traceable to sewers are very frequent. Yet he shows how in the same house one may see cases of dysentery, ty-

phoid fever, and diphtheritic sore throats, all due apparently to a common poison.

This should be admitted, says Jacobi, unless we assign a triple character to the poison, or banishing the belief in specific influences, simply attribute the causation of these diseases to the lowered tone of the system, and after this manner affording to morbid influences an opportunity to exercise their power.

The following case, in my personal experience, has in this connection some interest. I was called to see a case of diphtheria in the practice of Dr. Smith Ely, New York. In regard to this case Dr. Ely in a letter dated March 12, 1894, reports as follows: "In a persistent search for a cause of diphtheria in the C—— children, some of the casing enclosing the drain-pipe in the water closet being removed, a piece of the pipe below the trap was found to be broken out, so that, of course, the sewer gas mingled freely with the air of the house. This state of things might have existed for a long time. There was another slight case of diphtheria in one of the other children at the same time. In September, 1891, the same child who had diphtheria so badly had typhoid fever. There were other cases in the neighborhood, however."

As is so frequent in similar cases, the possibilities of causation in infectious diseases are rarely single, or always definitely separated from one another.

In certain families, diphtheria and follicular tonsillitis show a tendency to spread even though the sanitary conditions are of the best.[1] The connection, moreover, between diphtheria and preceding throat affections is occasionally most marked. This is probably the most important link between various insanitary conditions and the diphtheria which sometimes breaks out amid them. In this sense defective house sanitation is often a cause of diphtheria by producing a morbid condition of the mucous membrane which favors the development of the specific bacillus, though in other instances there is reason to believe that the specific bacillus might be present in the sewers of a district, and thence gain access to a house.[2]

Moreover, now "many are entertaining the view that different microphytes may produce the same disease, or that the same microphyte is subject to modification in virulence and in its products, and that disease may be influenced by the quality, as well as by the quantity, of the invading irritant."[3]

Once the sewers have become infected they may perhaps continue to be so for an indefinite period. If, then, for any reason, the plumbing fixtures of a particular domicile are defective, it is readily appreciable how sewer-air laden with disease germs finds access to it.[4]

Observation and experience have further taught us that sewers, if not properly constructed and carefully attended to, are more detrimental to health than if there were none at all.[5]

On the other hand, it is certain that in many instances diphtheria does not require for its development any of the ordinarily considered anti hygienic conditions. So far as we can determine accurately, the growth of the infectious element of the disease is not invariably favored by bad air or imperfect ventilation. Witness the facts reported by Jenner,[6] who states that he has seen more cases of this disease in hospital than in private practice; and again, as showing how little the untoward course of diphtheria is thus influenced, we note that whilst half of Jenner's hospital cases died, more than half of his private cases died.

These opinions of Jenner are in a measure corroborated by the results of a careful comparison of a large number of cases of diphtheria, reported in Massachusetts (Jacobi). Among the conclusions of the official report we find that "The contamination of the atmosphere of the bed-chamber by the emanations from sewers requires further study."

In this connection Dr. Arthur Newsholme, Medical Officer of Health for Brighton, England, states that diphtheria had increased in England latterly, and more particularly in urban districts.

"In this particular it differed greatly from other diseases of zymotic type, which had been much mitigated in severity by sanitary improvements."[1]

If this fact be admitted, it is additional proof perhaps that diphtheria depends for its spread on contagion direct from infected materials. The presence of sewers favors its continued existence. Closely inhabited localities do the same thing also, by furnishing ready means for communication of the disease. Thus in most cities it has become endemic.[2]

Elsewhere[3] in speaking of tonsillitis, I have said: "It is perhaps a less familiar fact that exposure to a vitiated atmosphere will occasion the development of tonsillitis in children. Septic causes of tonsillitis are also often met with, and I am constantly advised of the fact that defective drainage may give rise to recurrent attacks of tonsillitis in children."

This statement seems to receive corroboration from Osler,[4] who writes, "Bad hygienic surroundings appear to have a direct etiological connection with the disease." In so many instances defective drainage has been found associated with outbreaks of follicular tonsillitis that sewer-gas is regarded as a common exciting cause. Bernabei has also found that in many cases of acute angina streptococci are discovered, and that these cases are epidemic and contagious.

Rendu and Bulloche are even of the opinion that all acute anginas are of bacterial origin, and similar opinions are held of late by many other observers.[5]

In many of these cases, according to Kingston Fox,[6] and Browne, the differential diagnosis from acute tonsillitis due to cold or other causes is made by the fact that the septic cases are bilateral in the beginning.

No doubt, as I have observed frequently, some children are rendered more susceptible to septic causes by the presence at the same time of a rheumatic habit or a strumous constitution. Nevertheless, whenever recurrent attacks of tonsillitis occur in a child, or among children in the same family, it becomes a duty to see to it that the basins, sinks, lavatories, drains, and pipes shall be examined as carefully as possible, to discover if there be any defect in the plumbing through which sewer gas may gain entrance to the house. It is important again to observe that frequently no doubt what is recognized as sewer-gas in our houses is the result of decomposition which takes place in the house-drains themselves, rather than the result of decomposition in the distant sewer forced into our houses through the connecting drain (Waring). It is doubtless a fact that in many instances the gases formed within the drain of a house are far more hurtful to health than the gases which circulate in the main sewers. This is frequently explained by the fact that pipes and drains of the house have become coated over with slimy deposits which in time are considerable, and because many of these soil pipes are never properly ventilated by a proper circulation of air.

A considerable degree of doubt exists in the minds of some practitioners about the evil effects of sewer-air on the throat. This arises probably from "the notorious fact that workers in sewers are remarkably free from disease, and particularly from affections of the throat." Indeed, in the numerous citations which I have referred to personally, I have found no case in which one of these men is said to have suffered from diphtheria or tonsillitis. In many of the cases of disease which have been reported,

the illness may have been only a coincidence,[1] and in no manner connected with their profession. It may also be said in regard to these cases of immunity that these men have become gradually acclimatized to their usual surroundings, and that the others who were unfavorably affected by the work in the sewers, had abandoned it and taken up employment of a different kind.

Whenever cases of diphtheria, follicular tonsillitis, or erythematous sore throat occur in a house where the plumbing is found to be defective, we should be careful not to ascribe these diseases necessarily to this cause. In what precedes it has been shown that throat diseases may, and often do, occur where the drainage is bad; they also occur where the sewerage is in perfect condition; they likewise appear where there is no sewerage at all to account for the outbreak. If the sanitary appliances are defective, we are naturally inclined to hold them responsible for the throat disease. And yet, as a fact, few of our city, or country houses, even of those owned by wealthy people, come up in their plumbing arrangements to the requirements of a careful sanitary engineer. Despite this fact, the throat condition of the majority of people remains tolerably good, and the percentage of those who suffer from diphtheria, or less severe disorders of the throat, is comparatively small. Again, there may be some cause of throat disease other than that of breathing sewer-air, which has been overlooked, and yet ultimately is proven to be the occasion of the outbreak. In illustration of this statement I would cite an outbreak of diphtheria in the village of Upchurch, England, which was finally attributed to the dust from the collections of refuse from London dustbins accumulated in the neighborhood, and when the utter absence of any other source of infection was affirmed.[2]

The chronic poisoning with sewer-air, especially in its relation with diseases of the throat, is, as we have seen, a subject to which considerable thought has been given, and yet the conclusions arrived at are uncertain. Still it would seem to be fairly well established by repeated observations that the breathing of sewer-air for any considerable length of time, and even though largely diluted, will occasion many of the throat affections. The clinical experience of numerous physicians, the evidence of sanitarians, all point strongly to this fact. It is also proven that evil effects of breathing sewer-gas on the throat depend not so much on the quantity as on the quality of the gas. If the sewer-air contain the specific germs of diphtheria, it may become the carrier of this disease. At another time, when the sewer-air contains no such specific germs, it will be the bearer only of follicular or erythematous tonsillitis.

It is probable that sewer-air may at times be inhaled quite a long period without developing any symptoms of throat disease. At a later period, when the sewer-air becomes laden with harmful germs, a throat affection of infectious type may occur with certainty. In children, when no specific disease germs are at work, the symptoms of chronic sewer-air poisoning are frequently those of catarrhal tonsillitis. In times of epidemics the catarrhal tonsillitis is apt to assume a severe or malignant type,[3] and a simple sore throat may, under the influence of sewer-air, assume a very serious and aggravated form. In children, particularly, the susceptibility to the influence of air polluted by sewage emanations appears to be greatest. They easily become languid, and may suffer from sore throat connected or not with diarrhœa or some other manifest disturbance of the digestive tract.[4]

People are more apt to suffer from the evil effects of sewer-gas during the night than during the day, when the body is undergoing active exercise, and when the rooms are better ventilated. This is the reason why we hear patients say so frequently that they have gone to bed perfectly well and have awakened during the night or in the early morning suffering from sore throat. It is quite possible that the ordinary putrefactive bacteria, when germinating in pent-up sewerage, may be the cause of the catarrhal sore throats produced by sewer-air.[1]

Finally, it must be obvious "that the effect oftentimes is practically the same whether the fermenting sewage is contained in sewers, or has soaked into the ground about the house. Both may pollute the air with the same gases and may produce like effects upon the throat. When furnace fires are used in the house, the gases from a sewer-soaked soil may be drawn into the rooms above, giving rise to all the injurious effects of sewer-air."[2] "Or the position of the air inlet of a furnace near a drain-opening or other source of contamination may allow foul air to pass into the heating chamber of the furnace and be distributed through the house," thus becoming the efficient cause of diphtheria, follicular tonsillitis, or other throat disease.

The following communication I am indebted for to the courtesy of Dr. A. Campbell White, House Physician at the Willard Parker Hospital, N. Y. Dr. White's report appears to me very interesting and instructive. Miss Graf, the nurse from St. Luke's Hospital, referred to by Dr. Campbell, was seen by me both during and subsequent to her attack of diphtheria.

"I believe the impression is or has been quite universal that the origin of epidemics or of individual cases of this disease could be traced to faulty plumbing or some other condition giving rise to escape of sewer-gas. That such a condition can be the primary cause of diphtheria we are now quite safe in denying.

"We are very positive in asserting that the Klebs-Loeffler bacillus is the organism at the foundation of every case of diphtheria, and we can be almost equally positive in saying that this germ cannot be found in sewer gas.

"If the drain-pipes are in a moist condition, as they almost invariably are, it is justifiable to believe that even though these pipes may be loaded with the bacilli of diphtheria, the gases escaping will not carry the infection necessary to produce this disease.

"We can take for an example, and I think it is a good one, the wards in our hospital. Here we have some fifty patients, every one of whom has the bacillus of Klebs and Loeffler in the throat or nasal passages. We can compare, for sake of argument, these throats to the sewer pipes, and the air these patients are constantly exhaling to the sewer-gases. Now the ward, of course, in spite of good ventilation, is constantly filled with the expired air of patients suffering, some of them, from the very worst forms of diphtheria, yet we have never succeeded in obtaining any Klebs Loeffler bacilli in the air examined, nor have any of the attendants, who live twelve hours out of twenty-four in these same wards, contracted the disease.

"We are very firmly convinced that to contract this disease direct contact is absolutely necessary. Therefore sewerage (containing the diphtheria bacillus) must come in direct contact with the patient by contaminating the water, or some other such manner, in order to be held responsible for an attack of diphtheria."

Nevertheless I do not hesitate in saying that constant exposure to sewer-gas is a very important element in determining the severity of an attack of diphtheria, and that in many cases it is the most important factor in bringing on a fatal result.

At the annual meeting of the Public Health Association, held in Baltimore in 1875, Dr. Noel, after citing many cases in his own practice to bear out his statement, said: "We do not say that this gas is the direct cause of diphtheria, croup, etc., in the sense of being the one and only efficient cause, but we do contend, and we defy criticism here, that in Baltimore City it has most assuredly been the one constant factor invariably present in the most malignant and well defined house epidem-

ics." We can give an excellent example in our own recent experience. I refer to the case of Miss Graf from St. Luke's Hospital, and the other two nurses who attended the family in Pennsylvania, a family of seven or eight members, living in a house where the plumbing is exceptionally poor, and, as the nurses testify, where there is a constant odor of sewer-gas penetrating the entire place. Now every member of this family, ranging in ages from under five years to twenty-seven years, contracted the disease, and every one died after a comparatively short illness. This is a most frightful mortality. The three nurses who attended these cases also contracted the disease, but immediately came to our hospital for treatment. Not one of them died, and only one developed into anything like the malignant form assumed undoubtedly by the cases in Pennsylvania. We can hardly attribute this difference entirely to treatment, nor can we say they did not have the same exposure, but I think we are justified in believing that this marked difference in mortality was more than a little influenced by the fact that the former cases were treated in a sewer-poisoned atmosphere, while the more fortunate nurses were cared for in a clean, well-ventilated ward in our hospital, where there is no taint of sewer-gas.

Another important point to remember is that we are now finding many people in the very best of health walking around with the Klebs-Loeffler bacilli in their throats displaying no signs whatever of diphtheria. Some of these people later develop the disease, in others the Loeffler bacilli disappear without having caused any trouble or inconvenience. The former have been exposed to cold, have developed a catarrhal inflammation of the respiratory passages, or in some such way the throat, previously immune, is rendered susceptible to the bacillus. Now such a person, with the necessary bacilli in his throat, breathing in from day to day the atmosphere laden with sewer-gas, is almost certain to develop diphtheria, and we can readily see how easy it is to say (not knowing that the patient had previously the bacilli in his throat) that such a person contracted his diphtheria from the gas escaping from a defective sewer-pipe, while, on the contrary, if he had not already the bacilli in his throat, he might have gone on indefinitely breathing this vitiated air without even developing the disease.

We have ample reason to believe that sewer-gas attacks the weak spots of the patient. Dr. F. Gordon Morrill mentions this point in the *Boston Medical and Surgical Journal* of 1884. Among the diseases brought on by sewer-gas in this way he mentions, besides those affecting the throat, rheumatism, gout, asthma, pneumonia, and even neurasthenia.

The influence of sewer gas upon diseases of the throat can be summarized as follows: 1. Given a patient with a so-called weak throat, subject to frequent attacks of quinsy, etc., expose him to sewer-gas, he will probably develop amygdalitis. 2. Given a patient in good health, with a throat containing Klebs Loeffler bacilli, expose him for any time to sewer-gas, and he will probably develop diphtheria; or 3. Given a mild case of diphtheria, expose him to sewer-gas, and the disease will assume a more malignant type.

Therefore, although sewer-gas plays an important part in the etiology of some throat diseases, it can by no means be held responsible as the primary all-efficient cause.

The following letter is also of considerable interest. I saw the last boy who died, in consultation with Dr. Chandler, and agreed entirely with him in regard to the diagnosis:

"South Orange, May 26, 1894.

"Dear Doctor: The history you desire is in brief as follows: In April, 1888, Mr. C—— built and occupied a house on —— Avenue, Orange, N. J. In April, 1890, his oldest son was very sick with diphtheria, but recovered. No unusual amount of sickness affected his family for two years later in this house. He then moved to another town.

"A Mr. G—— occupied the same house after Mr. C—— vacated. He had a family of three children. All had been previously well. They soon sickened of various disorders of no especial name or magnitude. After living in the house about one year one child developed diphtheria, and after a week's sickness died.[1] About a month later, a third child was attacked with the same disease. By the advice of their physician they left the house on the third day of the child's sickness, but that child also died.

"The plumbing and draining of the house were found to be defective, the wash tray in the butler's pantry was without a trap. Mr. C——, who first lived in the house used the tray, but always kept the plug in the outlet and there was no overflow. Mr. G—— did not use the tray, and the plug was often out, and a 'bad odor' was noticed from the tray.

"An outlet pipe, to remove surface water which might collect in the cellar, ran directly to the cesspool and was also without a trap. Thus there were two vents from the cesspool directly into the house.

"These are, briefly, the facts without comment. They speak for themselves.

"Very truly yours,

"William J. Chandler."

THE PHONOGRAPH: ITS PHYSICS, PHYSIOLOGY, AND CLINICAL IMPORT.[2]

By J. MOUNT BLEYER, M.D.,

NEW YORK.

VISITING SURGEON TO THE NEW YORK THROAT, NOSE, AND CHEST HOSPITAL; LARYNGOLOGIST GERMAN WEST-SIDE CLINIC; MEMBER ROYAL ACADEMY, NAPLES, ITALY, ETC.

Before I enter upon a demonstration of the underlying principles and the action of the phonograph, let me occupy a moment of your time by recalling those special characteristics of the human voice, the distinguishing qualities of musical tones, etc., which it is necessary to keep before us in order to thoroughly understand the instrument I intend to dissect, both anatomically and physiologically before you.

You are all more or less familiar with the phonograph. Five years ago it was a closed book to us. To-day we presume to know it from preface to appendix. I fancy there are many here in this section who casually know me from the few years of work I have done in experimenting with the machine and the fragments that from time to time have gone forth to the profession from my pen and workshop. I can almost hear them say: "Here he is again; what can he have to tell us now?" My answer is simply to let you know the further stage of perfection to which I have been able to carry the recording and reproducing with integrity the sounds and tones which, aside from their general scientific importance, must soon become a valuable assistant to us in the positive recognition of disease.

All sound begins in those collisions and attractions among material things by which their parts are thrown into tremors. These are almost as various in quality as the properties of material substances. The sounds we hear are but indices to the vibrations of bodies from which they proceed, and the multitude of such terms as splash, roar, ring, thud, crack, whiz, squeak, crash, illustrate the marvellous diversity of characters which material vibrations may take. In the production of noise the thrills of matter are transient and irregular, but when prolonged and regular they give rise to musical sounds. Vibration depends upon elasticity, and bodies which are capable of the protracted and measured pulsations of music must, of course, be highly elastic. All bodies vibrate differently, and this depends upon the nature, form, and magnitude of the mass in motion. The vibrations of bells differ with their sizes and the metals and alloys which compose them; while wooden and me-

[1] Another child was stricken with a light attack of the same character before the first child died, but recovered.

[2] Read before the International Medical Congress, Rome, 1894.

tallic tubes, strained strings, and stretched membranes, illustrate the same thing.

Take a tuning-fork and set it into vibration by drawing a violoncello string across its prongs; the fork yields its own characteristic note, which will be loud or soft in harmony with the manner in which the fork has been set into vibration; so long as we use one fork only, it is obvious that the only vibration which can be produced in the sounds confines itself to a vibration of their intensity. If the extent of the vibrations be small, the sound resulting is feeble; its loudness increasing with the excursion of the prongs. What is true of the tuning-fork is true of any musical instrument, and hence the loudness of musical sounds depends upon the amplitude of the vibratory space of that which produces it. Now take two tuning forks, differing in the pitch, and let us presume that one is just an octave above the other. They may be excited in such a way that the notes emitted are of equal loudness, the only point in which they differ being in pitch.

We all know that the pitch of a fork depends upon its rate of vibration, which we can readily measure with suitable apparatus, and thus it is comparatively easy for us to accurately determine the pitch of a tuning-fork, and should we so test the two tuning-forks in question we would find that the notes of the one of increased pitch would vibrate twice as fast as the other. If the one, say, makes one hundred oscillations per second, the other, an octave higher, would make two hundred in the same interval of time, thus we may be assured that the pitch of any note depends upon its rate of vibration and nothing else.

So having accounted for two characteristics of a musical note, let me come to the third, which is of equal, if not greater, importance, and by no means so easy of explanation. I refer to what we generally term the "quality." The French have the more comprehensive term for it; they call it "timbre," while the Germans have the most exact defining word in the term "klang-farbe."

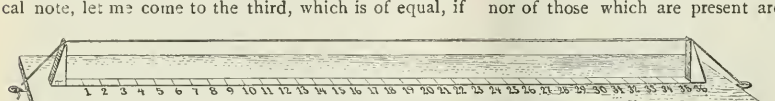

FIG. 1.—A stretched string showing a pendulum motion which makes only a given number of vibrations in a fixed time.

Klang-farbe is that which constitutes the difference between a violin or an organ and a piano forte, or between two human voices; indeed we may say between any sounds, musical or otherwise, which are of the same pitch and loudness, but readily distinguishable from each other.

To explain the physical cause of quality let us suppose we have a thin metallic wire stretched between two points over a sounding board (Fig. 1). When plucked at the centre the wire vibrates over its entire length, a loop being formed between the two points. The note emitted by the wire when vibrating in this manner is called the fundamental note. If we should dampen the wire at the centre by laying across it a feather or quill pen, and pluck it at a point midway between the centre and one end, both halves would vibrate in the same manner and independently of each other. That is to say, there will be two vibrating segments and a point of rest or node at the centre. But the rapidity of vibration of each segment will be twice as great as that of the wire when vibrating as a whole, and consequently the note emitted will be the octave of the fundamental.

When damped at a point one-third of the length from either extremity, and plucked half-way between that point and the nearer extremity, the wire will vibrate in three equal divisions, just as it vibrated before in two divisions; but now the rate of vibration will be three times as great as at first, and the note produced will be a twelfth above the fundamental. Similarly, by dampening and plucking it at suitable points, the wire may be made to vibrate in four parts, five parts, six parts, etc., the rate of vibration increasing to four, five, six, etc., times what it was at first. For example, let us assume that when the wire was swinging as a whole, and sounding its fundamental note, the number of oscillations performed in a second was 100. Then we see that, by taking suitable precautions, the wire can be made to break up into two, three, four, five, six, etc., vibrating segments, the rates of vibrations being respectively 200, 300, 400, 500, 600, etc., and the series of notes emitted being the octave above the fundamental, the fifth above the octave, the double octave, the third and fifth above the double octave, and so on. We now come to an important point, which is this—that, the wire being free, it is practically impossible to strike or pluck it in such a way as to make it vibrate according to one of the above systems alone. It will vibrate as a whole, wherever and however it is struck; but this mode has always associated with it or superposed upon it some of the other modes of vibration to which we have just referred. In other words, the fundamental note is never heard alone, but always in combination with a certain number of its overtones, as they are called. Each form of vibration called into existence sings as it were its own song, without heeding what is being done by its followers, and the consequence is that the sound which reaches the ears is not simple but highly composite in its character. The word "clang" has been suggested to denote such composite sound, the constituent simple sounds of which it is the aggregate being called its first, second, third, etc., partial tones. All the possible partial tones are not necessarily present in a clang, nor of those which are present are the intensities all the same. For instance, if the wire be struck at the centre, that point cannot be a note, but must be a point of maximum disturbance; hence all the even partial tones are excluded, and only the off ones, the first, third, fifth, and so on are heard.

That characteristic of a musical note or clang which is called its quality depends upon the number and relative intensities of the partial tones which go to form it. The tone of a tuning fork is approximately simple; so is that of a stopped wooden organ-pipe of large aperture blown by only a slight pressure of wind. Such tones sound sweet and mild, but they are tame and spiritless. In the clang of the violin, on the other hand, a large number of partial tones are represented; hence the vivacious and brilliant character of this instrument. The sounds of the human voice are produced by the vibrations of vocal bands, aided by the resonance of the mouth. The size and shape of the cavity of the mouth may be altered by opening and closing the jaws and by tightening and loosening the lips. We should expect that these movements would not be without effect on the resonance of the contained air, and such proves upon experiment to be the fact. Hence, when the vocal bands have originated a clang containing numerous well-developed partial tones, the mouth cavity, by successively throwing itself into different postures, can favor by its resonance first one overtone and then another, at one moment this group of partial tones, at another that. In this manner endless varieties of quality are rendered possible. Any one may prove it himself by making the experiments, that when singing on a given note he can only change from one vowel sound to another by altering the shape and size of his mouth cavity.

The Propagation of Sound.—Having thus briefly indicated the physical causes of the various differences in musical notes and the production of sounds by the organ of voice, I will now devote a few moments to consider how these sounds are propagated through the air and

reach the delicate diaphragm of the phonograph, while recording any kind of sounds.

Now, in order that all these multifarious and diversified tremblings of natural objects may be brought into relation with animate creatures, a common medium of communication is necessary. The air around us is such a medium. It possesses the marvellous power of taking up the numberless and ever-varying thrills of material objects and conveying them through space with all their peculiarities. The sensitiveness of the air (if I may so speak) to the faintest tremors in material objects, and its power of transmitting their individual qualities, are most wonderful. It drinks up the infinitesimal motions of things and diffuses them swiftly, simultaneously, and in countless myriads in all directions around.

That air is the medium of sound is proved by the fact that when vibrations occur in space void of air the silence is not broken. If a bell suspended by a string in a vacuum be struck, nothing is heard, although, if it is in contact with the jar, the vibrations are communicated to the outer air and sound produced. That air transmits the kind of motion that it receives is also proved by the fact that it will take up vibrations at one point and communicate them to a distant object that is capable of vibrating in the same way.

The velocity of impulses in the air which produces sound has been well established, and all kinds of shocks —the firing of a gun, notes of a musical instrument, or the voice, whether high or low, harsh or soft—all move at the same rate. The velocity is not affected by changes in atmospheric pressure or moisture, or by rain or snow, but it is affected by wind and by temperature.

The speed of sound is 1.090 feet per second at the freezing-point, and increases about one foot per second for each degree of ascent on the Fahrenheit scale. Sound moves in air with about the speed of a cannon-ball, and at a rate ten times greater than the swiftest motion of air in a hurricane. The sound produced in the open air tends to move in all directions with equal speed, but this tendency may be disturbed by various conditions. If the whole mass of air is moving in one direction, sound will travel faster with it than against it. In still air the sound of a musket-shot will be heard farthest in the direction of the impulse. Experiments have shown that a person speaking in the open air can be heard about equally well at a distance of 100 feet in front, 75 feet on each side, and 30 feet behind. When an obstacle checks a sound in one direction it can be heard farther in others, because, as a given amount of force produces a given amount of motion if the motion is arrested in some directions it is increased in others.

We have now seen that air is the common vehicle of sound, and that the sound impulses move in all directions at a high speed. But what is it that actually moves? The particles of air certainly not shot from the vibrating body to the ear, for then we should live in the midst of storms ten times more violent than tropical cyclones. The wonderful elastic properties of gases here come into play. The vibrations of bodies produce waves or pulses in the air. When a disturbance is produced at any point in an aërial at rest, sonorous undulations spread out from that point in all directions. These undulations are the effect of the rapid vibratory motion of the air particles. The analogy of water waves will help us to understand what is taking place under these circumstances. If a stone be dropped into the still surface of a pond, a series of concentric circular waves are produced, each wave consisting of a crest and a hollow. The waves travel from the centre of disturbance, while the drops of water which constitute them have an oscillatory motion in a vertical direction. That is to say, following any radical line, the water particles vibrate in a direction at right angles to that in which the wave is propagated. The distance between two successive crests or two successive hollows is called the length of the wave; the amplitude of vibration is the vertical distance through which an individual drop moves. In a similar manner sonorous undulations are propagated through air by the oscillatory motion of the air particles. But there is this important difference between the two cases, that in the latter the vibrating particles move in the same direction in which the sound is being propagated. Consequently such waves are not distinguished by alternate crests and hollows, but by alternate condensations and rarefactions of the air, the transmission of which constitutes the transmission of sound. The wave length is the distance between two consecutive condensations or rarefactions. It depends upon the pitch of the transmitted sound being shortened as the sound is more acute, while the extent of vibration of the air particles increases with the loudness. Such are the peculiarities of the vibratory motion in air corresponding to the pitch and loudness of the transmitted sound. But what is there in the character of the motion to account for the difference in quality? A little reflection will show that there is only one thing left to account for these, and that is the form of the vibration. Let us mentally isolate a particle of air, and follow its movements as the sound passes. If the disturbance is a simple one, produced, say, by the vibration of a tuning-fork, the motion of the air-particle will be simple also, that is, it will vibrate to and fro like the bob of a pendulum, coming to rest at each end of its excursion, and from these points increasing in velocity until it passes its neutral point. Such, however, is clearly not the only mode of vibration possible. If the disturbance be produced by a clang comprising a number of partial tones of various intensities, all excited simultaneously, it is obvious that the air-particle must vibrate in obedience to everyone of these tones. Its motion will be the resultant of all the motions due to the separate partial tones. We may imagine it starting from its position of rest to move forward, then stop short, and turn back for an instant, then on again until it reaches the end of its excursion. In returning it may perform the same series of to and fro motions in the opposite direction, or it may move in a totally different way. Nevertheless, however complex its motion may be—and as a rule it will be exceedingly complex—its periodic character will be maintained. All the tremors and perturbations in one wave will recur in all the others.

Could we see what takes place in a room when a tuning-fork is in vibration, giving out a "single note," we should behold all the particles of the air agitated in tremulous sympathy, and filling the space with swiftly expanding spheres of spectral beauty. Or were the effect produced by several instruments played, we should see forms in countless variety carving the air into ever-changing figures of geometrical harmony, and creating the perfect music of geometrical forms. Such a revelation is impossible from the swiftness of movement, which would baffle the eye; but it would be also impossible, because the complications of movement would confuse it. But where the optical sense fails the auditory sense succeeds. The membrane of the ear receives the torrent of motion and transmits it with all its harmonies. In an orchestra, where scores of instruments are playing through the whole compass of the scale, the air is cut into waves or pulses by every complexity of vibration—grave tones mingle with shrill, soft with harsh, fundamentals are merged in overtones, and the storm of impulses is shot with the speed of rifle bullets against the diaphragm of the phonograph as against the tympanum; and yet there is no confusion. In all their infinite diversity of qualities the waves are graven upon the little membranes.

In order to complete the physics in this paper, I cannot pass over it without paying some attention to visible sound.

The idea of getting a visual expression for musical vibrations occurred to Chladni, a physician of the last century. He fastened a plate of glass by its centre, and then, having scattered some sand over the surface, threw it into sonorous vibration by means of a violin bow

(Fig. 2). The plate when thus set in vibration, the sand was tossed away from certain parts of the surface and collected in other parts, forming regular geometrical figures. The plate, like a string, has one rate of vibrations which belongs to it; but again, like a string, by "dampening" it with a touch of the finger or fingers in different points along the edge the note changes, and with it the figure made by the sand. The lines on the plate where the sand settles are nodes, the lines of comparative rest. The violent agitation in the parts left bare can be shown by mixing a little lycopodium powder with the sand; this is excessively light, and is caught in the little whirlwinds of air generated about the vibrating segments.

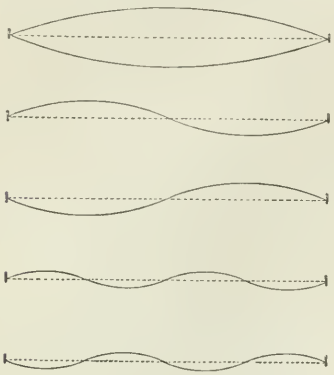

FIG. 2.—Showing the to-and-fro excursion of a plucked string.

A little instrument invented by Professor Sedley Taylor, and called the phoneidoscope, gives a most exquisite illustration of music made visible. He says that by this contrivance it is possible, by means of a soap film, to get different figures for different pitches, for different intensities, and for different qualities of tone. I did not find this instrument to answer in practice.
